This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

VOL. XXXV. ST. LOUIS, MO., JANUARY, 1907. No. 1

Editorial.

Bossism.

This seems to be the age of Bossism. The working man is bossed by the Union Labor system with its walking delegates. He is told how many hours to work and what wages to demand, taking away from him all the personal liberty which was guaranteed him by the Constitution and founders of this Government. They are now trying to boss the medical profession, telling the doctor what he must do and what he must not do, but they are finding this a rather hard job, for the reason that the average physician is an intelligent man, knows his rights and dares to maintain them. Of course, the more ignorant a man is, the more easily he is bossed. Nowadays somebody is always trying to pass a law to make others do as he wants them to, forgetting that this is a government of individual liberty, and that every man has an equal right to an opinion of his own. Bossism can only exist permanently in a monarchy, and not in a republic.

Bosh.

All this sensational talk by politicians and newspapers of the evils done by trusts is bosh. It is an undeniable truth that trusts have greatly benefited this country, and are today one of the prime causes of our wonderful national prosperity. Large industrial corporations can accomplish results impossible to the small manufacturer, because the cost of production is lowered when articles are manufactured in large quantities. Larger profits enable the corporations to pay higher wages, and this is of advantage to the community because it puts more

money into circulation. Consolidation of firms in the same line of business provides the necessary capital for conducting experiments that lead to new inventions and improvements of all kinds that add to the comfort and pleasure of life. So many everyday conveniences and luxuries are the result of enterprise that required the expenditure of large sums of money before it was finally successful. Wages in this country, home of the trusts, are higher than in any other country, and are also higher than ever before in the history of the world. Will the people allow the influence of scheming politicians and the "yellow" press to inflame them against conditions that are distinctly favorable? We say what we believe on this subject, in spite of the fact that the Editor of the BRIEF does not own a dollar's worth of stock in any trust, consolidation or syndicate.

Can Not Be Done.

Some of the large chemical houses pretend that they can analyze anything and make anything that anybody else makes. Of course, it's a lie, pure and simple—they simply want to substitute their own preparation and get the benefit of the good name of the other man's specialty. There are ninety per cent of the organic preparations that can not possibly be analyzed, because there are no tests laid down for them. It is common sense to suppose that a man who makes a special kind of cake can make it better than a man who only makes a cake once in awhile. The man who manufactures a special axe can make a better one than the man who manufactures every variety of tools and mechanical implements. This is the common-sense view of the thing, and the fight on specialties is as senseless as anything well can be.

The Cause of Wrecks.

The fight by the Government and politicians against railroads is the reason we are having so many more wrecks nowadays than we used to have. The large majority of the stock of railroads is owned by poor people and people of the middle classes. Of course the railroads like to be able to make a good showing on earnings and dividends, so they economize to such an extent on the wages paid employes that the natural result is incompetent and inefficient service. The shrewd financiers saw that this fight by the Government and politicians would hurt the railroads, and for that reason they put their stock on the market. It was bought by people who wanted to get a good return on their money, but did not foresee the effects of this fight by the politicians. The fight on particular lines of business is un-American. This Government is founded on the idea that the individual is everything, and the government nothing more than a protection against crime, but we are fast losing our idea of the liberty of the individual.

Between the Devil and the Deep Blue Sea.

The tendency of the Republican party seems to be to monarchy, and the tendency of the Democratic party to socialism. Between the two, the average conservative citizen is between the devil and the deep blue sea.

WE have been asked the question whether the chemists of this country are as good as those of Europe. It is a well known fact that the chemists of America and England are the best in the world.

Pulmonary Tuberculosis.

A Pennsylvania subscriber writes us as follows: "I have a son afflicted with pulmonary tuberculosis, having reached the hemorrhagic stage, who is about to leave for Colorado Springs. I seek this opportunity to ask if you will request the readers of the BRIEF to give their opinions regarding the relative value of the climate of Colorado Springs as compared with that of Arizona, New Mexico and California for combating this disease."

We feel sure that a discussion of this kind will also be appreciated by many other readers, and so let us have your views on this subject.

THE MEDICAL BRIEF

J. J. LAWRENCE, A. M., M. D.,
EDITOR AND PROPRIETOR,
NINTH AND OLIVE STREETS,
ST. LOUIS, MO.

NEW YORK OFFICE, ASTOR COURT BLDG.
FOREIGN OFFICE:
AUCKLAND HOUSE, BASINGHALL AVE., LONDON, E.C., ENG.

Vol. XXXV. January, 1907. No. 1

These rates include postage.
Advertising rates sent on application.

All subscriptions will be discontinued at expiration unless renewed.
The Medical Brief will not be sent unless paid for in advance.
One Dollar per year in advance.

Write *only on one side* of the paper.
See how *short* and *plain* you can write.
Write articles intended for publication, and matter for editor, *on separate pieces of paper.*
Articles sent for publication in the MEDICAL BRIEF *must not contain more than seven hundred words.* Short, practical, *brief items* always wanted.
The MEDICAL BRIEF is mailed on the first of each month. If a number fails to reach you we will supply it, provided we are notified within a month.

☞The Editor is not responsible for the articles of contributors. The MEDICAL BRIEF aims to publish articles on both sides of a question.

MEDICAL BOOKS.

We supply any MEDICAL BOOK, no matter by whom published, post-paid, on receipt of publisher's price. Send for our Catalogue.
Address, MEDICAL BRIEF, St. Louis.

The MEDICAL BRIEF has the largest paid circulation of any medical journal published anywhere.

[Written for the MEDICAL BRIEF.]

The Treatment of Hemorrhage by the Use of Drugs.

BY WALTER E. DIXON, M. A. (CANTAB.) M. D. (LONDON.)

Professor of Materia Medica, Pharmacology and Therapeutics in Kings's College, London; Assistant to the Downing Professor of Medicine in the University of Cambridge. London, England.

So much misconception exists respecting the pharmacological action of the drugs commonly employed for the arrest of hemorrhage that I have thought it desirable to give some account of their modes of action, especially with respect to their relative effects on different vessels.

They may be conveniently divided into two categories (1) those which act topically by constricting the blood vessels, and (2) those which are absorbed and pass into the circulation before reaching the seat of hemorrhage.

When it is possible to apply a drug directly to a bleeding point the hemorrhage may, as a rule, be stopped with certainty by bodies which either coagulate proteid or constrict the bleeding vessels. The tannins and ferric chloride may be taken as examples of this group, and they act by blocking up the smaller vessels with the precipitated serum-proteids. This principle of treatment is correct, and such drugs may be employed beneficially in hemorrhage from the stomach, the nose, the uterus, or other parts where the drug actually comes in contact with the bleeding point. As examples of the second group adrenalin, cocaine and digitalis may be mentioned. When the drug is absorbed and passes into the blood before reaching the seat of hemorrhage, exactly what happens to the bleeding vessel is not easy to determine. First it is necessary to know what has become of the drug; has it, for example, undergone any change in the body which renders its action inert? Secondly, supposing the drug to have reached the blood, and to have retained its activity as a vaso-constrictor, it must exert its action on the vessels of the bleeding point, but not more on these vessels than on the other vessels of the body; and supposing the bleeding vessels in question are poorly innervated or poorly supplied with muscle, the effect on the other vessels may entirely overshadow the effect on the bleeding vessels, so that the large increase in blood pressure from the former effect may overcome the constriction of the more feebly innervated vessels.

The tannins, as is now well known from the work of Stockman and others, are not absorbed as such into the system; not more than about one per cent reaches the blood in the form of gallate of sodium. Gallate of sodium does not constrict vessels; indeed, any tendency it

has on their caliber is always on the side of dilation, nor does it increase the tendency of the blood to clot, so that the tannins can not be regarded as drugs of value in the treatment of internal bleeding. The active principle of the suprarenal glands has been described as exerting a decided action in checking internal hemorrhage, even when administered by the mouth. We know that adrenalin is destroyed in the stomach, and that none of the active constituent reaches the blood; at least, there is no evidence of its absorption, as shown by vaso-constriction or rise in blood pressure. I have verified these statements both in animals and on man; in the latter sixty minims of one in one thousand adrenalin well diluted, produced no effect on the blood pressure, as recorded by the Hill and Barnard instrument, whilst in animals even larger doses have been given by the mouth without producing vascular changes. But if even a quarter of a minim of a solution of this strength is injected into the circulation of a cat, or if two minims are injected into the circulation of a man, there is a decided rise in blood pressure, acceleration of the pulse, and the other signs of suprarenal action. Even when adrenalin is injected subcutaneously it produces no effect on the systemic blood vessels. I have tried this by injecting under the skin of the forearm ten minims of a 0.1 per cent solution, and simultaneously observing the blood pressure on the opposite arm. The pressure remained constant. Similar effects have been observed by Janeway in America, and Elliot in Cambridge. The adrenalin produces a local effect, and is apparently destroyed locally. So that neither tannin nor adrenalin, when administered in the manner described, can reach the blood in a form in which it is possible for them to influence the vaso-motor system.

There are several drugs which induce vaso-constriction of internal vessels. Adrenalin, administered intravenously, will do this, and ergot, the digitalis group of drugs, lead and other substances are effective when administered, either by the mouth or subcutaneously. This vaso-constriction does not affect all the vessels in equal degree; some may be intensely constricted, whilst others, from an absence of nerve supply or poor development of the muscle in their walls, may remain almost or entirely unaffected.

In considering the condition of the blood vessels in any organ of the body, two factors must be noticed: (1) the general blood pressure, and (2) the tendency to constriction produced by the local action of the drug on the organ. The latter effect can only be obtained by perfusion of the isolated organ with defibrinated blood outside the body, for it is only in this way that the general effect of the drug on the other vessels, resulting in their constriction, and so of a general rise of blood pressure, can be avoided. Such experiments invariably show us that the vessels of the splanchnic area become constricted much more intensely than those of the muscles brain or lungs.

If one may take a hypothetical case in which a drug is producing constriction of the vessels by acting on their plain muscle fibre, it will produce intense constriction of the splanchnic vessels, a somewhat smaller constriction of the vessels supplying the skeletal muscles, and a still smaller constriction of the lungs, liver and brain. This effect in the lungs, brain or liver is so feeble that the tendency to constriction is overcome by the rise in blood pressure from the more intense splanchnic constriction, so that instead of constricting, these vessels dilate, and the organ becomes congested. This statement is true for all the drugs in common use which are employed to produce vaso-constriction. The vessels of the intestines and splanchnic area constrict most, then follow the skeletal muscles, kidney, spleen, uterus, etc., and lastly, the liver, lungs, brain and coronary vessels. The lungs and coronary vessels receive no nerve supply to their muscles, whilst that to the cerebral vessels and liver is of the most meager description, if, indeed, it exists at all.

We are now in a position to examine in further detail the effect of those drugs which produce vaso-constriction. Adrenalin is the first, and this drug, as already shown, induces a specific action only when it is injected into the circulation. It has been shown that adrenalin acts upon the sympathetic nerve-endings in the muscles, and, therefore, it induces vaso-constriction just in proportion to

the development of these endings. Thus the constriction of the vessels of the splanchnic area is intense; it is less in those of the limbs, very feeble in the cerebral vessels, and absent in the coronary. Hence, supposing a dose of adrenalin is administered intravenously to a man, the blood pressure rises mainly as the result of the constriction of the splanchnic vessels, and the blood being squeezed out from these vessels collects in certain organs, the vessels of which do not respond to adrenalin—*i. e.*, which are not innervated—especially the lungs, and to a less extent the liver and the brain. Not only are the vessels of the lungs and the brain not constricted, but they are in a state of considerable congestion.

Adrenalin has a decided action on the heart by acting on the sympathetic endings; it beats much more quickly and vigorously, and I have often, by continued administrations of small intravenous injections, kept an animal poisoned by toxins alive which, when these injections are stopped, dies immediately from cardiac failure. I mention this fact to draw attention to the powerful cardiac action of adrenalin, which might be invaluable in tiding over an emergency, and which has not yet received proper therapeutic recognition.

The use of ergot in the treatment of hemorrhage is also much misunderstood. It produces constriction of the vessels through its action upon certain nerve centers. It does not, like adrenalin, act on peripheral nerve endings; this has been shown by many observers, and I have verified their statements by perfusing the drug through peripheral vessels which, in all cases, tend rather to dilate than to constrict. Ergot, acting through the nervous system, produces effects somewhat similar to those produced by intravenous injections of adrenalin. Whilst it gives rise to intense constriction of the splanchnic and limb vessels, it induces congestion of the liver, lungs and meninges. There is another fact about ergot which has not received adequate attention. I refer to its action on the heart. Under the influence of this drug the vigor of the heart increases, and its output is augmented. This action is on the cardiac muscle, since the effect can be produced on the isolated heart. It is quite a different effect from that of digitalis, since there is no slowing of the beat, and no action on the vagal mechanism. The effect is considerable, more pronounced than that of digitalis, and thoroughly deserves the attention of clinicians. The objection to the use of ergot in any form is its want of uniformity; much on the market is quite inactive, and much has so feeble an effect as to be useless in the treatment of disease. Until it is suitably standardized these objections must continue to hold.

The great difference between the action of adrenalin and that of ergot, is that the effect of the former drug is very transient, being oxidized in a minute or two, whilst that of ergot is much more prolonged, the effect lasting several hours after the administration of a single dose. The practical effect of injecting ergot into a man is to produce a rise in the systemic blood pressure much greater than that which can be obtained by any of the digitalis group of drugs. This increase of pressure is mainly vaso-motor, but is partly cardiac. The vessels which do not constrict are the coronary, cerebral and pulmonary, so that the lungs and brain, being congested, any bleeding from them will certainly be augmented. Injections of ergot are legitimate for the purpose of arresting hemorrhage only when the lesion is in some part of the splanchnic system.

Of the digitalis group of drugs three only require attention—digitalis, strophanthus and squill. Squill is much the most effective in constricting vessels, then follows digitalis, and, lastly, strophanthus, so that if the use of one of these drugs be desirable for vaso-constriction, that one should be squill. Now, squill produces its action on plain muscle in two ways—first, by exciting the nerve endings, and, secondly, the muscles; so that vaso-constriction does not, in this case, depend upon the presence of vaso-motor nerves. But, nevertheless, the effect of dosing with squill is much the same, as far as the vessels are concerned, as dosing with ergot—that is, the splanchnic vessels constrict, and the pulmonary and cerebral dilate passively. The latter vessels are relatively poorly supplied with muscle, and when the blood pressure rises

the feeble attempt which the drug makes to diminish their caliber is overcome by the augmented blood pressure. On the coronary vessels the same order holds, as Dr. G. S. Haynes has shown in this laboratory—that is, the squill is most active as a vaso-constrictor, and strophanthus least. This is particularly interesting because strophanthus is far and away the most toxic drug to the ordinary musculature of the heart, a good tincture of strophanthus being eight or nine times as toxic as a good tincture of digitalis, and yet it has comparatively little effect on the muscle of the heart vessels.

There are still other drugs which are occasionally used for their effect on vessels. They are veratrine, barium and certain of the heavy metals, particularly lead. These drugs act directly on all forms of muscle, and produce tonic contraction. Hence they produce considerable and very persistent constriction, lasting longer than that produced by a nervous action. But, again, what has already been said about squill applies also to these drugs; it is doubtful if they produce other effect than passive congestion of the liver, lungs and brain. Their only legitimate use is for intestinal, uterine or other hemorrhage from the splanchnic vessels, and even here it may be questioned whether their action is desirable.

I maintain that the tannins, adrenalin, digitalis and its allies, ergot, veratrine, barium and lead, are all worse than useless for hemoptysis or hemorrhage from the brain or the liver. Upon what drugs, then, can the physician rely in these conditions? First, it is of the utmost importance to prevent any stimulation of the heart or vaso-constriction, either of which may be produced very readily reflexly by any mental disturbance. The most efficient prophylactic is to diminish all sensory reflexes by means of morphine. Morphine has no action on the heart or vessels directly, but by inducing quietness, placidity and a desire for sleep, it prevents sudden movements, excitement, and other effects which induce cardiac acceleration and reflex rise of blood pressure. In this way it will probably do more good than any other drug.

There is another type of drug which it is possible to employ advantageously, that is one which augments the clotting power of the blood. Calcium is par excellence the drug for that purpose. It should be administered preferably in a dissociable form, such as the chloride. If the salts of calcium are taken by the mouth a certain time must elapse before sufficient reaches the blood to produce an effect on its time of clotting. Unfortunately, however, most cases of bleeding are urgent, and such that the administration of calcium by the mouth is of little value. In these cases the drug should be given subcutaneously. One or two grains administered in this way will diminish the time of blood-coagulation of a healthy man to about a half. For this purpose the calcium chloride should be neutral, and injected deeply into the subcutaneous tissue, so that as far as possible the local irritant action of the drug may be avoided. In these cases of hemorrhage perfusion with saline is occasionally performed. Dr. C. J. Coleman has lately shown that such dilution of the blood increases the time of clotting sometimes to two or three times that of normal. Perfusion is, however, rarely undertaken until the bleeding has ceased.

I should like to point out that it is a well known clinical fact that most cases of internal hemorrhage, such as hemoptysis, stop without assistance. It is not possible to draw correct conclusions as to the action of a drug from its administration in two or three isolated cases of bleeding. The cessation of hemorrhage after the exhibition of a drug, is, in itself, no proof that the effect was produced by the drug, and I cannot doubt that in many instances where such drugs as ergot have been employed to stop hemorrhage, that their action has been rather to delay the desired effect.

Intercostal Neuralgia and Neuritis.

We have had requests for treatment on these troubles, and would be pleased to have our friends give their opinions. Give something practical for the benefit of all and thus lend your aid to those who suffer from these distressing maladies.

[Written for the MEDICAL BRIEF.]

Peripheral Neuritis: Its Etiology and Treatment.

BY EDWARD MACKEY, M. D., (LONDON), M. R. C. P.

Late Senior Physician to the Sussex County Hospital; Physician to Royal Alexandra Hospital and Professor of Materia Medica and Therapeutics Queens College, Birmingham. Brighton, England.

For a long period of years, certainly from the early sixties, when I was associated in work with Francis Edmund Anstie, Julius Althaus, and Sir Walter Foster, I have been keenly interested in the subject of Multiple Symmetrical Peripheral Neuritis in its various forms and modifications. But I must confess with all humility, that in my early Birmingham days I knew very little about it. This, perhaps, is hardly surprising, for, although an admirable description of alcoholic paralysis was given by Lettsom in 1789, I am much afraid that his work had not then come under my notice. My ignorance was great, but I trust I have since atoned for it, and there is this to be said in mitigation that it was on a par with that of most of my contemporaries. In those days our standard text-book of medicine consisted of the admirable "Lectures on the Principles and Practice of Physic," by Sir Thomas Watson. Glancing, after this long lapse of years, through the two volumes of his fifth edition, published in 1871, I find no clear description of the disease. He speaks of various forms of paraplegia, and describes them in his characteristic and masterly manner, but he seems not to have realized that neuritis is a factor to be considered. In 1868 there appeared the second volume of Russell Reynolds' "System of Medicine," dealing with the diseases of the nervous system. Reynolds was then professor of medicine in University College, London, and a man of much learning. He entrusted the article on Neuritis to Warburton Begbie, of Edinburg, who, I fear, failed to make the most of his opportunities. He recognized, however, that loss of power, partial or complete, as well as various morbid sensations, might be due to disorganization or other permanent changes in the trunk of a nerve as the result of inflammation. He noted that the nerve most liable to this change was the sciatic, but he failed to distinguish clearly between sciatic neuralgia and sciatic neuritis. Even my friend, Anstie, in his classical article on Alcoholism, in the same volume, although on the fringe of the subject, unhappily failed to realize its importance. Those, however, were but early days; and those physicians were pioneers in the world of neuro-pathology. It is probable that Duménil, of Rouen, was the first to demonstrate the existence of neuritis by autopsy, but it was not till the researches of Lancereaux, in 1871, of Eichhorst, in 1875, and of Jeffroy, in 1879, that the pathology of the disease was placed on a firm scientific basis. Long anterior to this, however, certain anomalous cases had fallen under my observation, patients whom I now recognize as having been the victims of alcoholic or some other closely allied form of neuritis. Less was known then than now about toxins, and every obscure pain was attributed to suppressed gout. People drank freely of good old fruity port, and if they hunted three days a week and died of a good old age it was no one's business to inquire too minutely as to the exact reason for their departure. Now everything is changed; the world has become abstemious, and if we suffer from alcoholic neuritis the finger of scorn is pointed at us, and we have to refrain from overindulgence in self defense. We have become more virtuous, or possibly, our powers of assimilating the juice of the grape are not what they were when the generation was younger.

Passing now from historical retrospect. I come to the description of the disease as I have met with it in many years of practice. Incidentally I may mention that it was in 1894 in the *British Medical Journal* that I published my well-known case of peripheral neuritis in a boy of six years of age. He, I am glad to say, was not alcoholic, although alcoholism in the very young is not an unknown disease. His neuritis was acquired in another way, and was the sequel of whooping cough, a rare condition, and one not usually recognized. The poison of pertussis is, however, just as distinctly a toxic agent as alcohol, arsenic, lead or any of the other forms familiar to us. Digress-

ing for one moment before passing on to the symptomology of the disease, I should like to point out that the vast majority of these cases, as met with, either in hospital or in private practice, are alcoholic in origin. It is a condition far more frequent in towns than in agricultural districts. The farm laborer in most parts of England drinks beer often in quantities which are by no means inconsiderable, whilst in certain counties, Devonshire, for example, cider takes its place. Yet amongst these people peripheral neuritis is practically unknown. In London and many of our large cities, the consumption of beer is on the decrease, and whisky has, to a great extent, taken its place. These whisky drinkers furnish us with the bulk of our cases, the patients being men engaged in business, commercial travelers, salesmen, publicans and the like. And yet, in Scotland, where whisky is the natural drink, and is daily and hourly consumed, there is much less neuritis. It is difficult to avoid the conclusion that the quality and character, not only of the form in which the alcohol is consumed, but the kind of whisky, have much to do with it. In Scotland, and the further we go north, this is emphasized, "pot still" whisky is the staple intoxicant. In England, and the further we get from Scotland, "pot still" whisky, except amongst the educated classes, is unknown, and the ordinary frequenter of the public bar or small hotel is supplied with a concoction which, although sold under the name of whisky, is, in reality, a "silent spirit," made not from barley, but from potatoes, rice, or any form of starch which renders itself liable to fermentation and subsequent distillation. That this form of ethylic alcohol is especially pernicious, and especially potent in producing neuritis and other forms of disturbance of the nervous functions, I have not the shadow of a doubt. I say, then, that alcohol is the most common cause of peripheral neuritis, and that of alcoholic drinks, silent spirit, under whatever name it may be sold, is the most prejudicial. Although alcohol is the most common form of toxemia, it by no means stands alone. Lead is another excitant, and it matters little whether it is taken in the form of contaminated drinking water or whether it is introduced into the system as a trade poison. There are very many occupations in which lead is freely used, and we meet with cases amongst painters, compositors, glazers of playing cards and workers in Brussels lace. Sometimes there is more than one factor at work, for example, a house painter may be a silent spirit drinker, and when he comes under our care suffering from neuritis, it is by no means easy to say which is the predominant factor, the whisky or the lead. In the same category must be placed arsenic, and I think mercury. Cases of chronic arsenical poisoning are by no means uncommon, and in most of them tenderness over the course of the motor nerves, with loss of co-ordination and a condition verging on paraplegia, is observed. Even when the drug is given medicinally, as in the treatment of chorea in children, the loss of patellar reflex is one of the first indications that the drug has been pushed to the limit of safety. There have been epidemics of neuritis from the drinking of beer contaminated with arsenic. These are all examples of inorganic or mineral poisonings, but scattered through the literature of the subject will be found references to the production of obscure cases of semi-paraplegia obviously due to neuritis after the administration, usually accidentally, of bisulphide of carbon, aniline, roburite and phosphorus. Peripheral neuritis also follows in the wake of attacks of many of the acute specific diseases, such as diphtheria, influenza, septicemia, enteric fever, and the like. I think, too, that it is not improbable that tuberculosis should be included in the category, although the evidence on this point is, to my mind, less conclusive. In still another category must be placed the poisons of rheumatism, rheumatoid arthritis, gout, and above all, diabetes mellitus. Many people nowadays regard Landry's paralysis as a form of neuritis, but I can not adopt this theory, and hold that it is due to a specific organism, probably a tetracococcus. From this brief review of the etiology of the subject it will be appreciated that there are very many forms of peripheral neuritis, some easily recognized, and some of an origin probably hitherto unsuspected. At present we are not in a posi-

tion, from their clinical features alone, to differentiate them. Lead poisoning is, as a rule, easily recognized, and the symptoms of chronic arsenical poisoning we all know, but over and over again we see cases which are difficult to assign to any particular category, and respecting the exact production of which, even after the most careful examination, it is impossible to give a definite opinion.

The symptoms, fortunately, present little difficulty, although they vary much in different cases. Amongst the earliest symptoms are numbness of the fingers and toes, vasomotor spasm in the fingers, and muscular cramps, especially in the calves. In acute cases there may be constitutional disturbance, with elevation of the temperature to 103° or 104° F. The patient may, for a time, follow his ordinary occupation, but at last has to take to his bed. The paralysis affects the extensors more than the flexors of the limbs, so that he is unable to extend the hand, and the toes are pointed as he lies in bed. The interossei and other muscles are weakened, and the diaphragm and the vocal cords are paralyzed.

The muscles atrophy, and the change is early noticed in the anterior tibial, the extensor brevis digitorum, the calf muscles and the interossei of the hand.

The electrical conditions are altered. The reaction to faradism is diminished or lost, but the effect of the galvanic current varies. Sometimes complete reaction of degeneration is present.

Sensory symptoms vary considerably—anesthesia is generally limited to the lower parts of the limbs, but there may be hyperesthesia; gnawing or burning pains belong, especially, to the early stages. The nerve-trunks are tender, there is extreme tenderness of the muscles to pressure, well-marked in the muscles of the calf. The reflexes are lost. The bladder and rectum are unaffected, but the excretions are sometimes passed in bed in alcoholic cases. As the case progresses, the skin undergoes trophic changes. Contraction of the limbs arise, such as flexion of the elbow, and pointing of the foot, and adhesions form in and about the joints. Bedsores are not common. In alcoholic cases the paralysis is generally accompanied, and sometimes partly masked, by a condition of mind of which the essential features are loss of memory for recent events, and delusions as to events that never happened. The patient may be unable to tell his name, age, the day of the week, or where he lives, but may say that he has been for a walk or ride in obvious antagonism to facts. There may be a stage of talkativeness, or even delirium; but for the most part the patients show extreme apathy and complete indifference to surroundings. Often the symptoms are marked by inco-ordination and ataxy instead of simple paralysis. It may affect the arms or the legs, and may simulate locomotor ataxy.

The diagnosis of this condition presents very little difficulty, and it is unlikely to be overlooked by anyone practically familiar with the clinical features of the disease. It is said that it may be mistaken for gout, but this is impossible in a well-developed example of chiragra or podagra. What it might possibly be mistaken for is the allied condition to which the term goutiness is often applied, a condition due to the presence in the blood of uric acid, or some other products of defective assimilation. Neuritis, it is true, has been confounded before now with diseases of the spinal cord, notably locomotor ataxy, incipient general paralysis of the insane, and even the early stages of disseminated sclerosis. It is to be remembered that the patient, when first seen, is either in bed or comes into the physician's office supported on crutches or aided by the arms of a nurse. It is difficult to elicit any characteristic gait, for the patient can not walk, but if the attempt is made, the legs are not lifted freely from the ground, and in any case the walk is not that which we associate with induration of the posterior columns of the cord. The condition of the patellar reflex will not help us, for it is absent, both in tabes and in peripheral neuritis. But really the diagnosis is not difficult, for, if we press the fingers firmly along the course of the motor nerves of the arms or legs pain is at once elicited, and the patient gives audible notice of his suffering and discomfort. In locomotor ataxy there are iridoplegia, and other eye symptoms, but these are absent in neuritis. The absence of hypertonia, of the

perforating ulcer of the foot, of the Charcot joints, of the gastric and other symptoms known as crises, will help us in coming to a correct conclusion. Moreover, in tabes there is in at least ninety-six per cent of the cases a well marked syphilitic history, whilst in peripheral neuritis this as often as not is absent. Hysteria, of course, has to be considered, but really, in the great majority of cases, with the aid of a little care and reliance on solely objective symptoms, no error can be made.

The prognosis is grave, not so much with regard to danger to life as the prospect of an early recovery and ability to resume occupation. It is not a question of days or weeks, but of months, and these are amongst the most chronic cases with which we have to deal. They are the despair alike of the patient and of the physician. We are compelled to deal with them gently and considerately, and they call for the exercise of much tact and, above all, patience.

When we come to speak of treatment we are on much more debatable ground, and it must be confessed that there are large numbers of cases which, for a time, seem to resist our best endeavors to afford amelioration to the pain. First and foremost the patient must be confined strictly to bed, not for a day but for weeks and months. The bed-room should face the sun, and should be as light as light can be. It is customary nowadays to laud the efficacy of light treatment, and it is undoubtedly useful, but the light should be not that of the arc lamp, but nature's light, the light and warmth of the sun with all the benefit which can be obtained from its actinic and life-restoring rays. Warmth is useful, but it is not necessary to heat the room with a gas stove, or some similar appliance. Cover over the patient with blankets and rugs, and open the windows wide, so that the fresh air may at all times beat on his head and face and invigorate him. Feed him well, for without this he will make no progress. Give him three pints of milk a day, with refreshers at intervals of beef tea and meat essence, not the potted variety, but the home-made article. Keep him amused, and keep him interested in all that goes on around him. Let him have the newspapers, give him books to read, and do not ignore the influence of friends and visitors. He has a long and dreary fight before him, and all that helps and encourages him must be regarded as a beneficial therapeutic agent. Lead him to look forwards, and not backwards, and remember that Hope alone can do much in paving the road towards recovery.

With regard to drugs, I am dead against the administration of morphine and all narcotic drugs. I could tell many a sad story of the harm I have seen inflicted by these baneful and pernicious agents. What benefits it if you cure an alcoholic neuritis and substitute for it the drug habit? The last state of the man is worse than the first, and harm has been done, and not good. To begin with, I would get his bowels open. I care little what agent is employed for the purpose, but get the bowels open, and keep them open. My own proclivity, especially when the tongue is brown and furred, and coated, is for calomel. Not, however, be it said, in small and nigling doses, but in substantial quantities, say ten grains to begin with, and more to follow. If the skin is dry and inactive, I give a few doses of sweet spirits of nitre, or of the solution of the acetate of ammonium.

These preliminaries having been adjusted, I improve the dietary, giving less milk and beef tea, and more solid food, such as steaks and chops, with a plentiful supply of vegetables. I entertain the old-fashioned belief that phosphorus is a nerve food and tonic, and I take care that articles of food containing this element are freely supplied. It might, I know, be given as a medicine in the form of hypophosphites or the glycerophosphates, but I am not very fond of medicines, especially for habitual use, and in chronic cases, and where possible, I rely on the judicious selection of food. A useful form in which to give phosphorus is a combination of casein with the glycerophosphates.

The patient having been duly catered, for we have to consider what we can do to allay the inflammation and relieve him of his sufferings. For this purpose there is nothing better than belladonna, and I find it an excellent plan to smear the legs with equal quantities of extract of bella-

donna and glycerin freely, and all over, and then on the top of that to apply hot fomentations. The relief afforded is almost instantaneous. Of course, the belladonna is liable to be absorbed by the skin, and to give rise to indications of toxic action. I presume that the physician is well acquainted with all the symptoms of belladonna poisoning; if not, he should adopt some milder forms of treatment, or better still, confine his attentions to cases of a less serious nature. Hot air baths, massage, electricity and various forms of mechanical vibration are useful, but care must be taken that the patient does not pass into the hands of an empiric.

With regard to drugs which are especially recommended for the relief of pain, I do not think much of them. I do not like synthetical products, those especially of the coal tar series. I have given from time to time antipyrin, phenacetin, exalgin and the like. Exceptionally they act admirably, but too often they produce the most disagreeable symptoms, even in what are supposed to be quite moderate doses, It is by no means a pleasant thing to have your patient coming out all over in an urticarial rash; it is by no means pleasant to be sent for hurriedly, and to find your patient with a weak and collapsible pulse, and perhaps cyanosed as result of the treatment. Possibly I am prejudiced, and slow to adopt new ideas, but I am careful and conservative, and do not care to use drugs which sometimes play me tricks, and are, to my mind, if not unsafe, at all events unreliable. I prefer to treat the patient himself, and not the disease. If there is anemia, I give iron, and cure it before taking other measures. If there is syphilis, and I am always keenly on the lookout for its manifestations, I know what to do. If there is a gouty diathesis, I rely on colchicum and iodide of potassium, whilst for dilated heart, with emphysema and chronic bronchitis, I find nothing better than strychnine and digitalis. This may seem very simple treatment, but it is the result of many years of experience, and I must in candor admit that my results have not been unsatisfactory.

[Written for the MEDICAL BRIEF.]

The Wastage of Child Life.

BY W. B. DRUMMOND, M. B., C. M., F. R. C. P., EDINBURGH,

Assistant Physician to the Royal Hospital for Sick Children, Edinburgh.
Edinburgh, Scotland.

Is there a wastage of child life? Everyone knows that the mortality amongst puny children is very high. But a high mortality does not, of necessity, imply anything that can properly be called wastage. Throughout the entire animal and vegetable kingdoms we find that a high mortality among young things is the general rule. The poet tells us that out of forty seeds nature often brings but one to bear. So far as many living things are concerned this saying greatly understates the case. Many plants bring forth seeds by thousands, yet their numbers do not increase from year to year. Every codfish in the sea is the sole survivor out of millions. If every little codling that hatches out of the ovum were to reach maturity, it would not be long before the sea itself would be unable to contain them.

Now, the modern biologist has taught us that this extraordinary mortality is no needless or purposeless massacre of the innocents. Heartless, though it seems, it is simply nature's way of securing the succession of generations growing ever fitter for life's race. Nay, it is by this very process that there have appeared on our earth, at length, consciousness, and intelligence, and joy, and love. Man himhimself, is a member of the animal kingdom, and as such, is subject to nature's law. No argument is needed to support the assertion that he can retain his proud position as lord of creation only on condition of his continuing to take part in the struggle for existence, only by submission to the law of the elimination of the unfit.

Let us admit, then, without further argument, that a certain amount of mortality among young children is inevitable. Let us admit that there are actually born into the world a certain number of babies whom no protecting care, no foresight, no knowledge, can safely guide and guard through the dangers of infancy and childhood. The

question still remains, does this number correspond to the number of babies who do die year by year. The facts of child mortality have only to be stated to enable us to answer unhesitatingly, "No." A great many of the children who are born die from preventable causes, and it is these deaths which constitute the wastage of which I am about to speak.

The facts of infant mortality.—When we begin to study the statistics of the mortality amongst young children there are three facts which strike us immediately. They are these: The greatness of the mortality; the variability of the mortality in different districts; the uniformity of the mortality in any district at different periods of time.

(1). *The greatness of the mortality.*—To the popular imagination childhood presents itself as a period of superabundant vitality and energy. We think of a child as a rosy, laughing, restless being, a creature endowed with a healthy appetite, a tireless spirit, and a nature redolent of sunshine and fresh air. Childish ailments are thought of, as for the most part, trifling incidents which scarcely interrupt the current of joyous, exuberant life. Disease and death one associates naturally with old age. The statistics of child mortality always bring with them a feeling of shocked surprise. It seems altogether out of the course of nature that the mortality among children under five should be greater than the general mortality at all ages; that the mortality amongst infants under one year of age should be much greater than that of children under five. Infants, it is true, are helpless, tender creatures, but are they not constantly watched by loving eyes and cared for by tender hands? Yet, in all countries called civilized we find that a large proportion of these little beings, after a few short months or weeks of life, pass on to join the great majority.

(2.) *The variability of the mortality in different districts.*—The exact proportion of the infants who perish varies greatly in different localities. From Dr. Newsholme's valuable work on vital statistics (1899), we learn that in England and Wales in 1896 the infantile mortality—that is to say, the number of deaths of infants under one year of age to every thousand births—was 147.5 per thousand. For the ten years, 1885-94, the infantile mortality ranged from ninety-eight in Dorsetshire, one hundred and four in Wiltshire and Westmoreland, and one hundred and nine in Berkshire, to one hundred and fifty-three in London, one hundred and fifty-seven in Durham, one hundred and sixty-one in Staffordshire, and one hundred and seventy in Lancashire. Among the great towns it ranged from one hundred and thirty-one in Huddersfield, and one hundred and thirty-five in Croydon, to two hundred and twenty in Burnley, and two hundred and sixty-two in Preston.

In Massachusetts, in the twenty years, 1874-93, the infant mortality per one thousand births, ranged between 172.0 (in 1875), and 152.4 (in 1877), the mean being 161.9.

In Hamburg the mortality under one year old, in the years 1882-96 per one thousand, living at this age, has ranged from 201.9 in 1894, to 368.8 in 1886.

(3) *The uniformity of the mortality at different periods of time.*—The difference in the mortality in different districts is not casual, as is shown by the repetition of the figures year after year. A district which has a high mortality one year will have a high mortality the next, and a district which has a low mortality one year will have a low mortality the next. The high mortality among infants is maintained in spite of improvements in sanitary conditions. There has been during recent decades a gradual lowering of the general death rate. This is shown in the improved "expectation of life." The latest figures dealing with this subject have just been published by Dr. J. C. Dunlap in the form of a supplement to the forty-eighth detailed annual report of the Registrar-General for Scotland. This deals particularly with the decade from 1891 to 1900. The figures show that the prospect or expectation of life has considerably and continuously improved during recent decades. A male child born in Scotland in the 1891-1900 decade, had, at birth, the prospect of living 4.35 years longer than if born in 1861-1870, 3.73 years longer than if born in 1871-1880, and 0.76 of a year longer than if born in 1881-1890. A similar improvement in the

promise of long life has taken place in favor of the female child. In the case of boys born in the last decade of the century, the average "expectation of life" had risen to 44.68 years; in the case of girls to 47.44 years, and for the two sexes combined to 46.01 years. An English inquiry tells a similar tale of growth in longevity. But in spite of this improvement in the general mortality, the death rate among infants remains extremely high. There has been some improvement here and there, but it remains true that a death rate equal to that among infants is not again experienced until the age of about eighty years.

The amount of the wastage.—The justification of the term wastage is furnished by the figures which show that the infant mortality is very much higher in some districts than it is in others. The general rule is that the mortality is lowest in rural localities, and highest in mining and factory districts; compare, for example, the mortality quoted of ninety-eight in Dorsetshire, as compared with two hundred and sixty-two in Preston. These are not extreme figures. In healthy suburbs inhabited by the better classes, the infantile mortality may be smaller even than in Dorset, while the figure of two hundred and sixty-two for Preston implies a considerably higher figure for the worst parts of that town. In other words, we find that under certain conditions only five or six babies die out of every one hundred born, while in others thirty, forty, or even more, will die. To the difference between these figures the term wastage may not unfitly be applied. The argument is that these babies die, not because they are not fit to live, but because they do not have a fair chance.

To this point we shall return again. But there is another aspect of wastage to which it is now time to refer. So far we have been speaking of wastage as if it referred merely to unnecessary deaths among children. But we ought to think not only of the children who die but of the children who survive. Are the children who live as healthy and happy, as fit for the labors and for the enjoyments of life as they ought to be? If they are not, here is wastage again in another form. Now, it is safe to say that wherever a very high infant mortality is found, there also will be found pale and stunted and delicate children; children who have indeed survived the perils of infancy, but who carry with them for life the effects of the unfair treatment they have received. A high mortality and a degenerate people go together, twin effects of the same cause. A high death rate, therefore, is only a partial indication of the total wastage of child life.

The causes of wastage.—The principal causes of infantile mortality are as follows:

(1). *Prematurity of birth, and congenital defects.*—A certain mortality from these causes is, perhaps, inevitable. Children are born, for instance, with congenital defects of the heart, which are incompatible with life, or which render the child so weakly that death results from some trivial ailment. We do not know the causes of such defects, nor can we prevent or cure them. Prematurity of birth, on the other hand, is to some extent preventable, inasmuch as it is more liable to occur when the mother has to work during her pregnancy, or when the conditions of her life are otherwise unfavorable.

(2.) *Hereditary causes.* — Such as syphilis, or alcoholism, or insanity, have an influence in increasing the death rate among the children. Nevertheless, the children of such parents may be perfectly healthy.

(3.) *Unhealthy environment* in early childhood certainly greatly increases the mortality. As we have seen already, the death rate of infants is much higher in towns than in the country, and in towns it reaches its highest figure where slum conditions prevail.

(4.) *The occupation of the mothers* is a factor in the death rate, for it has been shown that in districts where many of the mothers are engaged in factory work a child's chances are not so good as in similar districts where the mothers are not employed in this way. Other factors, of course, co-operate, for it is obvious that if mothers resume work soon after recovering from labor the infants will necessarily be deprived, at least partly, of their natural nourishment.

(5.) *Inexperience, ignorance and carelessness on the part of the mothers.*—An

extraordinary large proportion of the deaths of infants results from disorders of digestion and nutrition. This means that the deaths are due to improper feeding. Not only are the children too frequently deprived of their mother's milk. but they are fed on all sorts of things which are totally unsuitable for them. There is no more frequent cause of disturbed digestion among infants than the common practice of giving them "just a little bit of what's going" at table.

Faulty feeding is, of course, only one of the fruits of maternal ignorance and carelessness, but it is the chief. And it should be realized that faulty feeding is not only a direct cause of death by producing such disorders as vomiting and diarrhea, but it also acts indirectly. A great many young infants die of convulsions, and in many instances these are the results of unsuitable articles of diet. Deaths from such disorders as bronchitis, and pneumonia, again may really be due to the child's vitality and power of resistance having been lowered by faulty feeding.

The remedy.—There can be no doubt that all that is being done by the health authorities to improve the sanitary conditions under which the people live, and to diminish the spread of infectious diseases, must have a favorable influence on the wastage of child life. Such authorities can insure a pure and sufficient water supply. They can condemn unsanitary property. They can compel landlords to put faulty drains in order. They can segregate cases of infectious disease. They are beginning to turn their attention to the problem of a pure milk supply. The employment of mothers and of prospective mothers periodically comes under discussion.

But, in spite of all that has been done the infantile mortaility shows very little tendency to fall. And if everything were done that can be done on present lines, it is probable that the improvement would not be very great. The fact of the matter is that we have been attending too much to people in the mass, and too little to the individual. And so it comes about that in the towns where the sanitary authorities are most vigilant we find people living under sanitary conditions which are too appalling for words. A pure water supply is a good thing, but it will not make people clean who have no wish to be clean. A pure milk supply would be a good thing, but it would not solve the problem of infant feeding. Model dwellings have their advocates, but there are people who would turn the best model dwellings into a slum in a week. The next step in sanitary progress must be to deal with the individual.

The application of this fact to the problem before us has resulted in some interesting experiments concerning wnich I shall proceed to give some account.

The first of these was carried out in the little commune of Villers-le-Duc, in France. During the years 1800 to 1893, the infantile mortality was very high. It is said that on an average one child out of every four died during its first year. The matter was taken seriously in hand. Rules were made which involved individual care of the mothers and supervision of the children. Free medical aid was provided for those who required it. A sum of money was also paid at the end of the year to the mother or nurse if the baby was produced in a healthy condition. The result of the regulations made was remarkable. For ten years no infant's death took place in the village. During fifteen years only one child was still-born.

The second experiment was carried out in England. It would be more correct to say that has been initiated, for it is still in progress. The seat of experiment is the large manufacturing town of Huddersfield, and its author is Mr. Broadbent, the mayor.

Mr Broadbent was much struck by the appalling large death rate which exists among infants in certain districts, and on setting himself to study the matter he soon became convinced that wherever the fault lay, it certainly did not lie with the babies, but with the conditions which surrounded them from their birth. And if the fault does not lie with the babies, if they are not lacking in vital force at their entry into the world, then it follows, to use Mr. Broadbent's strong language on the subject, that the babies do not die. They are killed.

In a lecture which the mayor recently delivered on this subject he declared that

overcrowding, slumdom, defective milk supply, employment of married women in factories, were all secondary causes in producing the existing dire effects among infants and children. The mischief rooted itself in ignorance and indifference, and, perhaps, in a degradation of the ideal of motherhood. The mothers themselves were not to blame. The blame laid with those who were responsible for their education and upbringing. Compulsory education has been in force in England for thirty-five years, and yet girls are allowed to grow up ignorant of the elementary duties of motherhood. How, then, can they be blamed if they are so ill-equipped to bring their babies safely through all the perils of infant life?

His remedy was to help the babies by helping the mothers. The mother herself is the only proper guardian for the child. For the mother's milk, for the mother's care, for the mother's love, there is no substitute at all. Whatever is done for the babies should and must be done through the mothers.

The plan which has been adopted in Huddersfield was tried, in the first place, in a limited district which is inhabited chiefly by factory workers, with a sprinkling of quarrymen, masons and laborers. The district has no congested population, and it has no slums. The population is five thousand three hundred and fifty-nine. The death rate for ten years has averaged 13.44, and the birth rate 19.39, whilst the infantile mortality figure has been one hundred and twenty-two per one thousand births.

Obviously this is a fairly healthy locality. A comparatively small number of married women go out to work, there being a strong public opinion against the practice. As the district is typical of many localities on the outskirts of manufacturing towns, it was decided to see if any appreciable effect could be produced on the wastage of infant life.

The plan adopted consisted in appointing a lady visitor as a sort of municipal god-mother to the babies. We gather that the experiment initiated as above described, has now been extended to the rest of the town. The ladies appointed as health visitors by the corporation now visit the children soon after birth, and leave a card of advice with the mother. The baby is then allotted to one of a band of voluntary helpers, who visits it periodically and exercises a kindly oversight upon it. These lady helpers do not administer charity, but they help the mothers with advice and sympathy. On various occasions, such as Christmas and Easter, little remembrances are sent to the babies, and at the commencement of the diarrhea season and at the onset of cold weather short personal letters of advice as to the precautions needful are sent to each mother through the post. Cases requiring sanitary attention are brought under the notice of the public health officials.

One part of the scheme remains to be referred to, and we have kept it to the last, because, when the experiment was first started, it received in the newspapers a too exclusive attention. This took the form of a promise to pay £1 as a birthday present to each baby born in the district above referred to between November 9, 1904, and November 9, 1905, on its attaining the age of twelve months. This promise was made by means of a legally drawn promissory note, printed on a card, on which was also given as much condensed good advice as could be compressed into the space. This card, of course, served the double purpose of exciting the interest of the mothers, and of serving as an introduction for the visitors to the various homes.

All this seems very simple. The entire scheme resolves itself into a friendly supervision of the mothers and babies. And the results? So far as the experiment has gone, the results are very good, indeed. As has been said, the average infantile mortality in the area originally included in the experiment has been one hundred and twenty-two for ten years; for the twelve-month period referred to, the figure is fifty-four. In other words, coincident with the measures described, the mortality has fallen to less than one-half. This is only an intermediate stock-taking, but as the time comprises a whole year with its varying seasonal influences, there seems no reason to doubt that an equally good or even better result will be obtained when a longer period has been

covered and additional experience has been gained.

The scheme thus happily inaugurated in Huddersfield, is so simple; it is so rational; it is so obviously on the right lines that there can be no doubt that good will be effected. How great the results will be remains to be seen, but there seems to be no reason whatever why other towns where there is a wastage of infant life—are there any where there is none? —should watch to learn these results before inaugurating similar schemes of their own. All that is wanted is a far-sighted, level-headed man whose heart is aglow with the spirit of the second of the two great Christian commandments. Such a man, in short, as Huddersfield possesses in its present mayor.

[Written for the MEDICAL BRIEF.]

The Umbilical Cord or Funis.

BY WM. H. HALLOWELL, M. D.,

Professor of Obstetrics Minneapolis College of Physicians and Surgeons, Medical Department, Hamline University. Minneapolis, Minn.

Umbilical cord or funis is the vital bond between placenta and fetus, composed of two arteries, one vein, the pedicles of Allantois and umbilical vesicle with surrounding Wharton's jelly encased in a sheath.

Average length, twenty inches, with extremes of no length to several feet.

Thickness, half-inch, but varying with amount of Wharton's jelly present.

Spiral aspect, from arteries winding around the vein. This may be absent or exaggerated.

Strength, expressed by breaking strain from five to fifteen pounds.

Attachments, to placenta on inner surface at middle, but may be eccentric or marginal, and other end to fetal abdomen.

Functions, duplex. The vein carries oxygenated nutritious blood from placenta to fetus. The arteries carry a carbonated waste-laden blood from fetus to placenta.

Both arteries and vein have a favorably increasing calibre in the direction of their blood currents.

Funic pulse is synchronous with the fetal heart-beat. Neither capillaries, lymphatics, nor nerves are present.

Anomalies.—Varying number of blood vessels. Forked or divided cord. Velamentous—attached to membranes before reaching placenta. Fused, interlaced and triple cords of twins. Unequal accumulations of Wharton's jelly. Vascular loops.

Excessive amount of Wharton's jelly calls for close ligation of cord at birth in order to compress the blood vessels, done by first pinching Wharton's jelly.

Absence of Wharton's jelly does not prove closed lumen of blood vessels.

Unequal accumulations and vascular loops may simulate knots. In forked and velamentous cord attachment there's danger of compression or rupture of blood vessels. The fused, interlaced and triple cords of twins may cause dystocia or fetal death. Tangling of cords in multiple pregnancy nearly always results fatally by asphyxia.

Pathological conditions of the cord are cysts occurring only after fetal death. May be serous or mucus from liquefaction of Wharton's jelly, or may follow apoplexy of the cord.

Calcarious degenerations generally due to syphilis.

Odema—Due to interference with circulation.

Syphilitic lesions — Indurated cord-thickening of vascular coats—gummata of external coat of vein—hypertrophy of arterial valves—stenosis by local periphlebitis.

Varicose veins may rupture and cause fetal death.

Inflammation of blood vessels.—Always due to septic infection which becomes systemic, and commonly fatal.

Thrombi (septic).

Hernia at umbilical end of cord.

Tumors, as myxoma, myxosarcoma, rarely sarcoma.

Blood extravasations.

Accidents to cord—Coils, knots, short cord (relatively) prolapse, compression, excessive traction, excessive torsion, rupture, strangulation by amniotic adhesions (due to oligo-hydramnion).

Coiling of cord around fetus, may include neck, body, limbs, or combine them.

It occurs about one in four pregnacies. Not dangerous, usually, but may cause fetal death.

Mortality, almost one per cent.

Around neck.—One to nine times reported.

Dangers.—Traction on cord and constriction of its blood vessels and cause asphyxia and cyanosis.

Fetal strangulation by compression of fetal neck, sometimes cutting through soft parts to spinal column.

The cord is compressed between nape of neck and maternal pelvis, so more dangerous in long labor, as in primipara, due to narrower birth canal than in multipara. More dangerous in male births—boys being larger than girls, and labor prolonged. Very dangerous in breech presentations, where compression of cord about the neck is added to the usual danger of cord compression between the maternal pelvis and the after-coming head. May change presentations, as vertex to face or transverse, due to traction or shortened cord, or neck coils, preventing flexion of head in mechanism of labor.

Coils around body and limbs may act as ligatures, and cause atrophy of parts beyond or intra-uterine amputation of a limb.

Coilings generally may result in a relatively short cord.

A short cord, naturally or relatively, is one that interferes with birth or drags on the placenta.

Dangers from short cord.—May cause hemorrhage by dragging on and detaching or tearing the placenta. Excessive traction on cord, with compression and closure of its vessels. Unusual pain at placental site. Retraction of presenting part between labor pains due to elasticity of cord. Uterine inertia from exhaustion in labor.

Rupture of the cord and fetal hemorrhage. Uterine rupture from strong ineffectual uterine contractions in labor. Uterine inversion from dragging on uterine wall.

Still births.—Trauma, hemorrhage and sepsis in the mother from manipulations to aid delivery.

Causes for coiling are long cord and all that allows very active fetal movements, as excess of liquor amnii, or small fetus.

Treatment for coilings.—Do not attempt to uncoil in the uterus, nor resort to version. At time of labor examine for loops about neck, and try to disengage by loosening and enlarging the loop. Slip over head. In some cases let fetus pass through loop. Often birth occurs without disengagement of cord, when sufficiently long. If impossible to loosen, apply two ligatures to the cord, cut the cord between them, deliver quickly, and resuscitate the child. If the cord should rupture during labor, deliver quickly and stop hemorrhage from cord.

Troubles from too long cord.—Coilings, knots, intra-uterine, compression and interruption of circulation, prolapse, cord entanglement.

Prolapse of the cord.—If it occurs before rupture of the bag of waters it is also called funic presentation.

There are different degrees of prolapse, from a small knuckle of cord in the cervix to a long loop hanging from vulva.

Causes for prolapse.—Abnormal pelvis, as faulty strait, causing imperfect adaptation of presenting part to pelvic inlet.

Faulty uterus, as shape—as large lower uterine segment. Position—as flexions changing axes of fetus and superior strait, and disturbing adaptation. Contractions—irregular.

Placenta attached low down, and cord nearer to cervix.

Faulty presentations as footling and transverse, and want of perfect adaptation of presenting part to lower uterine segment.

Twins.—Very often one is transverse.

Excess of liquor amnii and sudden rupture of bag of waters and escape of cord.

Cord caught on presenting part. Hydramnion and lower uterine segment flaccid. Relaxed uterus of multipara.

Dangers from prolapsed cord.—Greater in vertex presentations, due to greater pressure between head and maternal pelvis.

If membranes are unruptured, there is no immediate danger.

Prolapse has no influence on labor to the mother, unless manual or instrumental assistance to delivery is given.

Sudden cessation of fetal heart sounds is a sign of fetal death.

The longer the compression the greater the danger, so anything that may hinder or delay labor is dangerous.

Treatment of prolapse of cord.—Preserve membranes from rupture until complete cervical dilatation occurs. Then resort to manual restoration of prolapsed portion, to perform which, place patient in knee-chest position to cause a negative abdominal pressure, and gently push the cord back. Even though restoration is accomplished, it may return. Remain in knee-chest position until engagement of presenting part, this will hinder cord from returning.

Other methods.—A tape passed through a catheter and carrying prolapsed portion to uterus, but it may return.

In breech presentation, bring down feet and hasten labor.

In transverse presentation perform version.

In undilated cervix and membranes ruptured, resort to manual dilatation and perform version.

If cord pulsations cease, fetus is dead: so don't risk mother by manual or instrumental interference.

Knots of cord.—Local accumulations of Wharton's jelly and vascular loops may simulate knots, called false knots.

True knots are single, double or complicated, loose or comparatively tight: formed in early or late months. Those formed in early months are tighter than those formed in later months: the early-formed are more apt to interfere with circulation, and can be distinguished when untied by lessened amount of Wharton's jelly present. Knots do not usually interrupt circulation nor interfere with fetal vitality, but may cause fetal death.

At times they may slip along the cord during delivery.

In multiple pregnancy the cords may knot and entangle, and cause the death of one or both fetuses.

Causes for knots are long cord, excessive amount of liquor amnii, small fetus, active fetal movements.

Funic Souffle, a sound agreeing with the fetal heart rate. It is considered a danger sign, and generally means interference with funic circulation in umbilical arteries. It occurs in about fifteen per cent of pregnancies.

In very thin women a souffle may be caused by pressure of the stethoscope.

Lesions of cord during labor.—Injury or rupture of isolated vessels or the cord may be ruptured from sudden jerk in rapid delivery, or in street labors, woman standing, or in spontaneous precipitate labor.

Ligation of cord.—When, in absence of emergencies, wait until cord pulsations cease; this varies from a few seconds to ten minutes or more.

The funic pulse ceases progressively from the placental end up to the umbilicus, sometimes having ceased at the former while still strong at the latter.

Its cessation is due to pulmonary respiration and retraction of the musculatum of the walls of the arteries, usually normally performed in mature, healthy children, but a slight asphyxia or weakened pulmonary action may keep the vessels full with danger of primary and secondary hemorrhage from the stump of cord—if it should be cut and not ligated. Waiting for cessation of cord pulsation also saves blood to the child, it being aspirated into its body by strong pulmonary action. And waiting also prevents, in great measure, the classic initial loss of weight soon after birth.

Some claim that cord ligation is unnecessary, in imitation of lower animals, as the cat, and also some medico-legal cases cited in which cords of illegitimate children were cut without ligature, and no hemorrhage following.

But as there are factors, as mentioned, which may prevent a physiologically bloodless cord, in every case the cord should be carefully ligated. This is especially necessary in twin births in which neglect of ligatures on the cord of the first child may cause death by hemorrhage of the undelivered child, due to blood connections between the two placentas.

The practice is to pass two ligatures and cut the cord between them. Hold cord in palm of hand when cutting to prevent injury to fetus.

Where ligate. — Usually about two inches from the umbilical end, so as not to include the skin extension on cord from fetal abdominal surface, and also

not to include a knuckle of intestine, sometimes present, which, if ligated, would result in a strangulated hernia.

Kinds of ligatures used.—Almost any kind, provided it be aseptic; but a broad tape is the best, because tight ligaturing with thin, round material, may cut through vessel walls and allow secondary hemorrhage. Also scissors and all other contact with stump should be aseptic as a prophylactic against septic absorption and a general fetal septicemia.

When the cord is torn off close to the abdomen, compresses are sometimes useful, but the best treatment is acupressure, using two hairlip needles, passed at right angles to each other through the skin, but not to include the abdominal wall, and figure of eight turns with thread or other ligaturing material.

Treatment of stump of cord.—With all aseptic precautions fold stump in dry borated cotton, sometimes dusting with boric acid, and protected from rough contact by external objects by the bellyband usually worn, remembering that disturbance of a desiccating cord may cause secondary hemorrhage.

Falling off of stump usually occurs in a few days, but may not be detached for a week or longer. On falling off an excoriated or ulcerated surface may be left, which treat with antiseptic solutions and a mild astringent, as bismuth subcarbonate, and dress the part twice a day.

Umbilical fungus is sometimes met with, which secretes a sero-purulent fluid, and heals slowly—not sensitive itself, but the surrounding tissues may become painful. As long as the fungus exists the granulating tumor can not heal.

Scissor or knife removal is contra-indicated on account of the great hemorrhage resulting.

Better cauterize with nitrate of silver and use a salicylic acid bandage.

L. W. Bremerman, A. M., M. D., of New York City, has been appointed professor of genito-urinary diseases in the New York School of Clinical Medicine, to fill the vacancy caused by the death of Professor William K. Otis, M. D.

[Written for the MEDICAL BRIEF.]

Congenital Syphilis.

BY WILLIAM H. DAVIS, M. D.,

Professor of Dermatology and Venereal Diseases in the Denver and Gross College of Medicine. Denver, Colo.

Transmission by inheritance is one of the recognized fundamental characteristics of syphilis. A study of the facts relative to the transmission of syphilis justifies the following conclusions:

1. A syphilitic father may beget a syphilitic child, the mother remaining free from all signs of the disease; she becomes immune against syphilis through the placental circulation of the embryo (Colles Law). She may, however, later suddenly show tertiary syphilis without any previous symptoms. She may also only remain immune during gravidity, and become infected at any later period. She may, on the other hand, become infected during the time the fetus is in utero.

The transmissive power of the father is restricted as compared to that of the mother. The transmissive power of the mother is much more potent, prolonged and pronounced than that of the father.

When both parents are syphilitic, and the disease is of recent duration, the infection of the fetus is almost inevitable. The more recent the syphilis the greater the probability of infecting the fetus, and the greater and more marked the manifestations on the offspring. Hereditary transmission is more certain when parental syphilis is in full activity, but may occur when no active symptoms are present, that is, during the period of latency.

Both parents may be healthy at the time of procreation; the mother may contract syphilis during pregnancy and infect the child in utero, but infection is not probable if the maternal infection is after the seventh month of pregnancy.

The syphilogenic influence may be modified by the type of the disease, the age of the diathesis, specific treatment, constitutional peculiarities and other conditions imperfectly understood which influence heredity in general.

Time has an attenuating influence on the diathesis; as the duration of parental infection increases there is a progressive

enfeeblement of the transmissive power as shown in successive pregnancies. Abortion takes place at a more advanced period of fetal development; finally they cease to occur, a child may be born viable, but syphilitic. Still later children may be born having no traces of the disease.

The syphilogenic influence of the father is rarely manifest after the tertiary stage, but in the mother it is much more prolonged and active, extending to the sixth or seventh year, or longer.

Specific treatment may hold in abeyance the syphilogenic influence of both parents. A woman may have one or more abortions from the disease; if she be subjected to active treatment and pregnancy should occur, she may bring forth a healthy child, and if, after this the treatment be suspended, the next child may be syphilitic. The modifying influence of treatment is by no means certain. (*Prince A. Morrow.*)

Hereditary syphilis may be differentiated from the acquired form by its mode of origin and certain peculiarities in its evolution. In acquired infantile syphilis there is a primary lesion at the point of infection, and it does not differ from adult syphilis except in increased severity from an enfeebled capacity of resistance.

In hereditary syphilis there is a simultaneous development of both superficial and deep lesions, vesicular and bullar syphilides are common, and there are other lesions that are its exclusive product, when they are found in the young infant, such as peculiar changes in the bones, dental malformations, eye lesions, as syphilitic ectropion and iritis. One of the earliest and most characteristic symptoms is snuffles, due to syphilitic ozena, which gives the child great discomfort on account of interfering with breathing and nursing. The child loses its plump, well-nourished look; becomes thin, and refuses the breast. The first appearance of the disease in children with no manifestations at birth, usually shows itself in the first month in a ratio of sixty-four per cent; second month, twenty-two per cent. The earliest eruption to appear as to the point of time, according to Miller, who, in the study of a thousand cases in a Moscow foundling hospital, is the bullous syphilides in twenty-five per cent of the cases, erythematous syphilides in forty-five per cent. The latter begins on the lower part of the abdomen as minute oval or round spots that disappear under pressure, and invades the whole body in a week; then the lesions take on the characteristic coppery color, which will not disapear on pressure. The papular syphilide and its modified forms of the mucous patch and condylomatalata are common congenital lesions.

Mucous patches are frequently seen at the junction of the mucous membrane and the skin, as on the lips and around the anal orifice. Movements of these parts give rise to painful fissures, which constitute a sign of hereditary syphilis. A fissure at the angle of the mouth is said to be almost pathognomonic of syphilis. Fissures occur in about seventy per cent of the cases (Miller). Mucous patches appear in the mouth and condylomatalata occur where two skin surfaces rub together, and are flat, fissured, and ulcerated, and exude an offensive secretion.

The pustular syphilide may be general, but is usually more pronounced on the face, thighs and buttocks; they tend to group about the mouth, and are said to be indicative of profound syphilization. Ecthymatous pustules may develop later in the disease.

Vesicular syphilides usually occur associated with bullous and pustular syphilides. They are a rare form of severe early congenital syphilis; they occur closely packed together in groups on the chin, about the mouth, on the nates, forearms, hypogastrium or thighs, and are situated upon infiltrated brownish red bases.

Bullous syphilides frequently exist at birth, or they are the first syphilide to appear, and indicate severe form of disease. Their site of predilection is on the face, palms, soles; they are at first filled with sero-purulent contents which soon becomes purulent.

The tubercular syphilide is rare, and always a late lesion. It may occur as early as the sixth month, but usually much later as a relapsing syphilide, very much as it occurs in the acquired form.

The gummous syphilide is the latest manifestation of the disease, and is sometimes met with in early adult life as a congenital lesion of syphilis.

Kaposi regards the characteristic symptom of hereditary syphilis a diffused infiltration of the palms and soles, the skin of which is uniformly brownish, red, dry, shiny and fissured.

Prognosis.—The death rate in acquired syphilis is small; it rarely causes death, but of hereditary syphilis it is murderous. It condemns the offspring to almost certain death. Intrauterine death of the fetus is the common result; this may occur at almost any period, but most commonly between the third and seventh month. The child may come to full term and be still-born. It may be born alive, but syphilitic. It may be born apparently healthy, but soon gives evidence of the disease. About one-third of all the syphilitic pregnancies die in utero; one-third born alive die in six months, and an analysis carefully compiled shows only about twenty-five per cent survive. (*Prince A. Morrow.*)

Intrauterine death is often the result of changes occurring in the placenta, also from atheromatous inflammation and occlusion of the umbilical vessels interfering with the nutrition.

The skin is often macerated, the epidermis lifted in patches, and often entirely wanting over large areas.

If the fetus has reached an advanced stage of development, characteristic changes are found in the epiphyses of the long bones and in the internal organs.

If there should be no manifestations during the first year, the child has probably escaped infection.

The New Psychology.

BY J. D. BUCK, M. D.,

Professor of Principles of Medicine and of Mental and Nervous Diseases in Pulte Medical College. Cincinnati, Ohio.

It would be an anachronism to speak at the present time of the science of medicine. Science means system, order, uniformity, certainty, and definite results. True, we have something of the methods of science, something of its achievements elsewhere, utilized in, and applied to, the study of both health and disease, and in the efforts to overcome its ravages. But empiricism is still everywhere in evidence, and uncertainty, confusion and often disappointment and disaster stare us in the face. The physician who is confident he can "cure" all his cases is either an inexperienced or shallow enthusiast, or a prevaricator. The physician of long experience and deep learning is apt to be the most ready to admit his uncertainty and frequent failures. People recover without aid of the doctor, and often die after much treatment and many consultations. All the way from "Christian Science," "Faith Cure," "Metaphysical Healing," down to "Dowieism," if the patient recovers the process employed, whatever it may be, is credited with his cure, and heralded accordingly. While death in any case is an "irresistible dispensation of Providence," plain and unmistakable. Nor can the most scientific physicians or methods be altogether acquitted of this empiricism, much as they may dislike or deny it. Perhaps its frank admission may be the most hopeful and certain release.

Now our ideas of disease and of health are based on the natural and inherent relation of structure and function, whether of any tissue or organ, or of the organism as a whole. Deranged organ implies deranged function, and vice versa. Histology, physiology and pathology here clasp hands. Nevertheless, we are frequently confronted by the fact that where grave disease exists, and death results, no appreciable or discoverable disorder of tissue or organ can be discovered. The theory is, however, that it must be there, whether we can locate or define it or not. This may be called the *mechanical theory of disease.* That it is, in a large sense, true, and that it has greatly increased our knowledge of pathology is true. But there is another side to the problem.

The foregoing method has led us into endless details; into categories of symptoms and pathological changes, such as require half a lifetime to master. The patient, *the man as a whole*, is almost lost sight of. Detail has led to specialization, so that a man's medical attendants are like the household attendants in the

old world, where caste defines and limits their duties, and they swarm like flies.

I am not denying any benefit or the finest achievements that have resulted from this drift of the times, though we may presently be compelled to halt and review the ground over which we have passed.

If the foregoing is true regarding our theory and treatment of disease in general, the defects are manifest in a magnified form when we come to mental diseases. Dropping for the moment recognizable diseases of the nervous mechanism, and regarding a very large number of cases of purely mental disturbance or alienation, we find our physiology, or pathology and our categories practically useless. We are driven from that view of the man of many parts—organs and functions—to that other concrete view of man as a *unit;* a *self-conscious, individualized intelligence.* Our categories seem practically useless, our patient is *insane,* and we know little of the "mind diseased," more than a name, and we often find neither cause nor cure.

Here lies the field of the new psychology. Recognizing all that our categories have taught us, and leaving this in the background, we are to study the modes and manifestations of the individual intelligence; the "Content of Consciousness." What it is, and how it acts, and the laws of its states and changes, can never be inferred or deduced from the study of the physiology and pathology of the nervous system. That the two are related goes without saying. We as yet no systematic knowledge of "the self and its states of consciousness," the purely psychological side of the problem. Not only so, but such knowledge is quite generally ignored, ridiculed or declared impossible. In other words, psychology, with the average physician today, is in the position that physiology occupied a century ago, when to *name* the "vital principles," was regarded as sufficient to explain all human phenomena.

Hypnotism has done something, when intelligently interpreted, to add to our real knowledge of psychology. But how seldom it is correctly and intelligently interpreted. There are three recent works that, taken together, illuminate this whole subject, viz., "The Great Psychological Crime," Professor William James' "Varieties of Religious Experience," and Mr. F. W. H. Myer's "Human Personality."

The new psychology is here launched in quite definite form, not on the boundless ocean of conjecture, but on a well-defined coast, with the chart of experience and the compass of experiment, fact, and law. Owing to materialistic bias, and contemptous and ignorant prejudgment, it may take twenty or fifty years for the average Sadducee among physicians to regognize the new psychology.

That a very considerable portion of the activities of man are basic, physical, and proceed from below the plane of action, is quite true. That another and very large, though exceedingly subtle group of activities proceed from above the plane of action—sift down into us from above, as lust and passion arise from below—is equally true. Hence, in the new nomenclature of psychology, we have the self, the *subliminal self;* and the *supraliminal self,* already adopted by the profession of leading universities.

Now, the bearing of all this new psychology on the recognition and treatment of mental diseases is already apparent. Our text books already contain the word *obsession,* which only a few years ago would have been simply sneered at, and our whole field of study in mental and psychic phenomena is being rapidly enlarged and illuminated as never before. Those who really care to *know,* need not be left in darkness, doubt or uncertainty.

A Plea for More Humane Treatment of Advanced Cases of Tuberculosis.

BY FRANK C. WILSON, M. D.,

Professor Chest Diseases Hospital College of Medicine.
Louisville, Ky.

A total lack of humanity on the part of the large sanitariums toward the advanced cases of tuberculosis should be a subject of very severe criticism. Their refusal to admit these cases can only be accounted for by their fear of "injuring" the statistics of their institutions. In-

cipient cases are gladly received, and occasionally a moderately advanced case will be admitted, but the advanced and hopeless cases are not wanted. It is very much to be desired that our wealthy philanthropists, in the disposal of their charity for the establishment of such institutions, should make it a condition that proper provision should be made for the advanced as well as the incipient cases, irrespective of their effect upon the statistics. If necessary, they could be grouped under separate classes, but for humanity's sake they should be taken care of. If this were done the public would be better protected, for this dangerous class of cases would be taught proper sanitary requisites, and the community to that extent protected from infection. At the same time the segregation of such a large number of cases will afford an opportunity of testing the various methods of intreatment suggested. Among the hundreds of methods of treatment now being exploited some may be very valuable, many are known to be worthless, and a clinical test of the best of these treatments by large institutions for the tuberculous would be of untold benefit to the physician and to the public. If every method proposed were subjected to careful, systematic tests at the bedside of a large number of patients, and a co-operation and comparison of results between these large institutions were possible, after a sufficient length of time definite conclusions could be reached which would clearly determine the value or the worthlessness of a given remedy.

No physician, however anxious he may be to properly test a method of treatment, can have the same facilities that are accorded the sanitarium observer. Much time would be saved by such a co-operation, and the public would be protected from charlatanry and imposition.

It is most desirable to discover some method of destroying the tubercle, if that can be done without injury to the patient. While the natural resistant powers of the patient are not sufficient to accomplish this unaided, the trend of opinion in the professional mind in recent years has been to simply depend upon the natural powers of the patient, aided by fresh air and food. That many incipient cases can be cured in this way it must be granted, but it is certainly a rational proposition that if we can in any way, without injury to the system, destroy any portion of the germs which are causing the disease, it is a thing to be desired.

In the moderately advanced, and also the more advanced cases, it seems folly to trust solely to nature's efforts, even though assisted by fresh air and food. With millions of germs multiplying so rapidly and destroying the tissues so extensively, overwhelming the system with poisonous emanations and sapping the strength of the poor victim, is it any wonder that death soon closes the scene in this unequal contest? Is it reasonable that physicians should calmly watch such a contest without at least making an effort to assist nature in her combat with these germs. The vitality of these germs can be destroyed by agents if there can be found any way of introducing them into the system in sufficient quantity to accomplish this purpose.

I have, for several years, made use in a number of cases of a method of treatment employing two of our best germicides, employing as a vehicle an artificial serum, the exact counterpart of the natural blood serum, which, when introduced intravenously in the circulation without protest on the part of the system, carries with it a germicidal action which will immediately destroy every tubercle bacillus with which it comes in contact. This fluid, conveying nascent chlorine and ozone, is introduced to the amount of one pint without disturbance to the circulation, passing to the right side of the heart, thence directly to the pulmonary circulation, and if only a moderate amount of pulmonary tissue is involved in the tubercular process, it will permeate every portion of this area, destroying all, or at least a large percentage, of the germs present. If only a small area is involved in the process, I have seen a single infusion bring about a complete disappearance of the tubercle bacilli from the sputum, and the constitutional symptoms subside, and the physical signs disappear. If a large area is involved, then some bacilli may escape destruction, and begin to multiply, and the constitutional symptoms return in a few

weeks. If a second infusion is made, the results are permanent in many cases.

It certainly seems reasonable that if such results can be secured by this simple plan of treatment directed toward the destruction of the germs, and which does not interfere in the least with the use of fresh air and food, we should take advantage of it. Treated in this way a large percentage of incipient cases can be promptly arrested, of the moderately advanced cases many can be cured, and even some of the more advanced can, if persistently treated, either be greatly benfited or possibly cured. Can we not in this way materially aid in our fight with the Great White Plague?

[Written for the MEDICAL BRIEF.]

The Non-Operative Treatment of Strabismus.

BY JOS. S. LICHTENBERG, M. D.,

Professor Ophthalmology, Medico-Chirurgical College, Now Consolidated with the School of Medicine, University of Kansas; Ophthalmologist St. Joseph's Orphan's Home, Home for Aged, Etc.
Kansas City, Mo.

Stimulated by a series of successful cases in the treatment of strabismus by non-operative methods, and by several recent publications by Jackson, Wurdeman, Worth and others, I deem it best that this short sketch should bring the attention of the profession to the fact that this ocular deformity is, in many instances, amenable to cure without surgical interference.

In the present day furore for operations, it is the tendency to rush into surgery to the neglect of other methods. True conservatism may sometimes demand immediate and timely surgery, but in the condition under consideration in the majority of instances, in fact, nearly all instances, the need of haste is conspicuous by its absence.

As a rule, I have had no difficulty with my patients, after laying the facts before them, to gain consent to use the non-operative methods.

To successfully correct the deviation of the eyes by non-surgical measures, I wish to emphasize the great importance of early treatment. Worth in his recent book cites two cases of infants which he had under his care at the early age of one year and five months. In both of these cases glasses were worn, and other methods used with success. Worth also reports one case at the extremely early age of five months. So that the advice commonly given by the family physician to wait until the child is older, he may outgrow it, etc., is wrong. Many cases which could have been cured by non-operative measures require surgical intervention later, and then only a cosmetic result achieved.

The present aim in the treatment of strabismus, by any method, is not only the cosmetic result, but to restore binocular vision. This is always the case where non-operative measures are successful, which cannot be said of the operative methods, because conditions have been established by waiting, which render this impossible.

As a rule, when strabismus has become established for any length of time, there is a great reduction of vision in the non-fixing eye, and this is known as amblyopia exanopsia. The exact pathology of this condition is not clearly understood, but the clinical fact remains that these eyes do not recover their visual acuity under any treatment. To this general rule, however, I have found many exceptions, especially in young subjects. It is the amblyopia combined with the loss of binocular vision that early treatment prevents, so it is positive that any case should receive proper attention as soon as the earliest symptoms are noticed.

The non-operative methods of treatment may be classified as follows: First, optical or the exact correction of errors of refraction. Second, the occlusive bandage. Third, the suspension of the accommodation of the fixing eye by a reliable cycloplegic. Fourth, fusion training or orthoptic exercises. Fifth, bar reading.

The exact correction of refraction errors is of first importance. The rule is that convergent cases are associated with hypermetropia, and divergent cases with myopia, so that it appeals to any logical mind that the correction of these errors is rational. The ciliary muscle must be under the control of a reliable cycloplegiac, and there is none better than atropia. As a rule I order a one per cent solution dropped into the eyes three times daily for

three days, and then examine or test the refraction. In young children the strength of the solution must be modified. In young children, also, retinoscopy is the method *par excellence* in estimating the refraction. I know that I can measure the error within .25 D, so that we have in this an accurate method in which the observer sees for himself, and is independent of the patient. In older subjects the results by retinoscopy are proved by subjective methods as a matter of accuracy in the routine of adjusting glasses. The glasses prescribed must be a full correction or very nearly so.

The occlusion bandage is applied over the fixing eye for variable periods, from a few hours daily to several days. It consists simply of a pad of gauze and cotton, held in place by a bandage or strips of plaster. The object of the bandage is to force the use of the non-fixing eye, thus exercising it, so to speak, and, in many instances, the vision comes up and the amblyopia exanopsia prevented. With the same object in view the suspension of accommodation in the fixing eye is next used. The cycloplegiac, almost always atropin, must be applied to the fixing or better eye only. It is a fact that, in many cases the eyes remain straight during the time the accommodation is suspended in both eyes, but the old habit of using one eye only is kept up. If the atropin is applied to the fixing eye only, this forces the use of the nonfixing or worse eye, especially in near vision, thus again forcing its use. After several months of this treatment the vision of the nonfixing eye usually comes up, and then we test by the usual methods, such as a red glass held over one eye, prisms, etc., and try to elicit a diplopia. If the diplopia is elicited, we know that both eyes are being used simultaneously, and then we are ready to use the fusion exercises.

For this purpose we have the orthoptic picture in one form or another. These consist of two halves, which when combined, make the complete picture. For the purpose of having the picture in the act of binocular vision, stereoscopes are used, and there have been invented by Oliver and others adjustable ones, but I have found the ordinary cheap hand stereoscope to answer all purposes. However, the best instrument as yet devised, is the amblyscope of Worth (see illustration).

This instrument, to follow Worth's description, consists of two halves joined by a hinge. Each half is made up of a short tube joined to a longer tube at an angle of 120 degrees. These tubes are 1½ inches in diameter. At the elbow of each tube is a flat oval piece, on the inside of which is fitted a mirror. At the end of each of the long tubes is fitted carriers to hold the object slides, which are again two halves or portions of a complete picture. At the ocular end of the instrument are two lenses of five inches focal length, the distance of the reflected image, and serves to render the rays of light emanating from the pictures at the other end of the tubes parallel. An adjustable arc connects the two tubes so that their angle of separation may be varied or adjusted to each case. The advantage of this instrument is that the illumination of the two halves of the

picture can be varied. By giving the half corresponding to the eye that has the lowest visual acuteness a stronger illumination, and *vice versa*, it is stimulated more than the fellow eye and encouraged in its use.

By exercising the eyes at stated intervals with the amblyscope at the office, and by using the stereoscope with the proper pictures at home, in favorable cases the case goes on to a more or less rapid termination.

Bar reading consists of a strip of metal or board, about one-half to one inch wide, bent so as to hold the strip a few inches above the level of the reading matter. This is placed over the middle of the page, vertically, the result being that to see a line of print as a continuous and unbroken one, both eyes must be used in the act of binocular vision. This can be used only in older children, and in my hands has been disappointing.

In conclusion, I wish to call attention to these facts:

1. The advice usually given parents in cases of strabismus occurring in young children, is to wait, that the child may outgrow it, etc. This is wrong and pernicious.

2. Treatment should be instituted at the earliest notice of the condition.

3. In every case non-operative means should be tried, if possible, for a sufficient length of time before resorting to surgery.

Abdominal Operations Without Fuss and Feathers.

BY W. A. FORSTER, M. D.,

Professor of Clinical and Operative Surgery, Kansas City Hahnemann Medical College; Consulting Surgeon and Gynecologist to Hospital for Women and Children, Etc. Kansas City, Mo.

It has been the custom of surgeons in general to purge and scrub the patient to death, depleting him by so doing until there is no resistance left. Notwithstanding the fact that Dr. Moynihan has demonstrated that he can practically rid the intestines of bacteria by free purging, by so doing he takes the vitality of the patient. From practical experience and observation, I believe that the less fussing you do with the patient the better, provided, you get him practically clean. It has been my custom never to purge a patient prior to an abdominal operation unless he be badly constipated, and in case an enema will not answer. Ordinarily I give him an enema just prior to operating, and I find that under these circumstances there is much more resistance left on the part of the intestines and patient in general.

And he suffers less from shock, and less from the terrible nausea following operation, and there is less intestinal prostration produced by constipation and paralysis. It is a fact that most of the cases generally pronounced by the surgeons peritonitis are intestinal obstruction, due to paralysis of the intestines caused by depletion.

Another point in the preparation of the patient is the matter of drink. It is my habit to give my patient a glass of water fifteen minutes to a half hour before operation, which will sustain him and prevent the terrible thirst, and do much to prevent nausea after operation. Of course he must abstain from solid food for several hours prior to operation.

In the matter of scrubbing a patient prior to operation, the popular custom of shaving and scrubbing with a stiff brush give rise to pain and excoriates the skin and permits the entrance of infection through the abrasions. I get just as good results from shaving the patient the night before the operation and then preparing him for operation while he is under the influence of the anesthetic. Instead of brushes I use gauze sponges, which will cleanse the skin fully as well and produce no abrasion of the cuticle.

The habit of flushing the abdominal cavity with saline solutions I seldom practice because if there is any pus present it is diffused through the whole abdominal cavity and offers a greater opportunity for contamination of all the viscera and you subject the patient to a greater risk of infection. My plan is to mop out as carefully as I can with dry mops, leaving the peritoneal cavity comparatively dry.

By carefully cleansing the peritoneal cavity, drainage is not only not indicated as it was formerly, but the patient makes a more speedy recovery.

The practice of depriving the patient of a drink of water after operation is not only cruel but harmful. I have seen patients suffer for days after an operation for want of some water to drink. I give my patients a sip of water occasionally (not too often, or too much), which not only adds to the patient's comfort but aids materially in the recovery.

One of the most dreaded conditions after operation is nausea. I have found that by flushing the stomach or allowing the patient to drink all the water he can, he not only vomits easier without strain or retching but thoroughly washes the stomach, and if he does not vomit the water will pass through and accomplish the same object. This has been my most satisfactory method of treating nausea, not by compelling the patient to suffer by depriving him of water to drink, but by giving him more.

Pleurisy and Its Relation to Tuberculosis.

BY FRANKLIN T. POEHLER, B. S. M. D.,

Professor of Diseases of the Chest and Clinical Medicine in Hamline University.
Minneapolis, Minn.

In this paper I refer to pleurisy only in its relation to tuberculosis. Pleurisy is an inflammation of the serous covering of the lungs or its reflection on the ribs and diaphragm. This inflammation is associated with more or less micro-organisms and frequently associated with the tubercle bacillus, either as primary tubercular pleurisy or secondary to tubercular disease of the lungs or other tissue; so that the question has frequently arisen whether pleurisy is not a cause of tuberculosis.

The ordinary mode of infection in tuberculosis is inhalation of the bacilli into the lungs, bronchi and air vesicles, causing tuberculosis directly or by the entrance of these bacilli into the lymphatic or vascular system, causing tubercular adenitis or inflammation of some of the serous membranes. The question arises then, what actually causes pleurisy and what is the final outcome? Of course, if all pleurisies were the starting points of tuberculosis then the future welfare of the patient might better be conserved by looking after and treating the predisposing condition, than by simply treating the local pleurisy. There are forms of pleurisy which are most undoubtedly tubercular, some even primary, others secondary to other tubercular processes and due to the invasion of tubercular bacilli into the pleura. We may have it first as an acute primary inflammation characterized by a sero-fibrous or purulent exudate. The onset of such an inflammation may be like that of an ordinary acute pleurisy or it may be insidious in its development like that of the latent form of pleurisy which eventually becomes tubercular.

Pleurisy may immediately precede pulmonary tuberculosis, be associated with it, or succeed it.

Second. As an acute pleurisy the result of extension from adjacent tubercular lung.

Third. A chronic, adhesive, proliferative tuberculous pleurisy characterized by great thickening and adhesion of the pleura, with tubercular infiltration of the thickened product.

A certain number of cases of consumption begin as tubercular pleurisy which invades the lung by contiguity or by blood infection. One of the most convincing facts in favor of the infection theory, which seemed established prior to the discovery of the bacillus by Koch, was the frequent occurrence of pleurisy as a forerunner of phthisis. It was held that the caseous product of pleurisy furnished the infectious virus, which, entering the blood, caused tubercle formation in various parts of the body. Thus one-third of the ninety cases of pleurisy, followed by Bowditch, terminated in phthisis. Prior to 1882 tuberculosis was supposed to be hereditary and little was known of its contagious character. In that year Koch revolutionized the accepted view of its etiology by demonstrating the tubercular bacilli.

Primary tuberculosis in a very large majority of cases begins in the lungs, and it is assumed that such cases are due to the inhalation of the bacillus of dried sputum in the form of dust.

Heredity as a causal factor in pulmonary tuberculosis is to be noted only as a predisposing physical deformity which is inherited. This departure from the normal may be noted in a general lack of resisting power to diseaase, especially a proneness to attacks of bronchitis, strumous conditions during childhood, abnormally narrow chests, in a flat thorax and lack of expansion of the upper lobes of lungs.

Likewise pneumonia, influenza and pleurisy are immediately predisposing factors, the inflammatory soil giving a good field for the tubercular germ.

Pleurisy may follow injury of the chest wall and lungs; chill from exposure to wet is an exciting cause. A weakly constitution and previous ill-health have a marked effect in lowering the powers of resistance to the influences that produce disease. This is especially evident in a liability to pleurisy among those who have a tendency to pulmonary tuberculosis. But in the majority of cases pleurisy occurs quite independently of any such conditions.

Examination of the effusion has shown that in many cases the disease is due to irritation of the pleural membranes by microbes, of which the most frequent are the tubercle bacilli, pneumococci and streptococci. But, of course, as in the case of pulmonary trouble, the inflammations increase the opportunity for the tubercle bacillus.

Out of forty-four cases of pleurisy examined, seven were purulent and thirty-seven sero-fibrinous.

In a series of sero-fibrinous pleurisies no micro-organisms were found.

The presence of staphylococcus pyogenes in a serous effusion does not mean that it will necessarily become purulent.

Absence of organisms in empyema points most probably to a tubercular origin.

Presence of diplococcus in serous effusion subsequent to pneumonia does not prove that they will become purulent.

Exclusive presence of Frankel's pneumococcus usually justifies a good prognosis, notwithstanding that a radical operation is best.

Of cultures made with fluid withdrawn from thirty-eight cases of sero-purulent pleurisy, twenty-eight remained sterile, while four showed pure colonies of staphylococcus albus.

Of the twenty-eight sterile, fifteen were cases of pleurisy and the affected region was the focus of a tubercular infection. One was a case of pleurisy developing into a case of pulmonary tuberculosis. Seven had suspicious signs at apex. Four were apparent cures.

In the bacteriological study of cases of sero-fibrinous pleurisy by Fesnet there were found:

Pneumococcus in twenty per cent of cases.

Staphylococcus in thirty per cent of cases.

Eberth bacilli of typhoid in five per cent of cases.

Tubercle bacilli in fifteen per cent of cases.

Undetermined in thirty per cent of cases.

Of one hundred and one cases of pleurisy examined, thirty-two were definitely tubercular, thirteen existed in patients with tubercular lesions of lung without definite proof of the tubercular character of pleurisy.

The pneumococcus cases on the whole ran a favorable course.

Those due to staphylococcus are more insidious in onset and terminate less favorably.

Cases due to Eberth's bacillus occurring in the course of typhoid are latent in their symptomatology and are often somewhat hemorrhagic.

The tuberculous forms tend to be dry and fibrinous. There can be no doubt that the tubercle bacillus is the most common cause of dry pleurisy and of pleurisy with serous effusion.

Many of those who recover from the effusion afterward suffer from the tubercular disease, especially of the lung. This termination is of too frequent occurrence to be merely a coincidence.

Many French observers believe that seventy-five per cent of all such cases are

of tubercular origin. This estimate is considerably higher than that of English or American observers, but the proportion of cases of tubercular origin is increasing year by year as the investigation of cases becomes thorough.

Examination of the effusions by culture methods often gives negative results; but inoculation of the serum into guinea pigs, where large amounts (fifteen cubic centimeters or more) of the serum are injected, is much more successful, many of them becoming infected even when the fluid appeared sterile.

Purulent effusions, if sterile, suggest tubercle bacilli as a cause; if not sterile it is probably always due to pneumococcus, streptococcus some other microbe.

Pleurisy due to pneumococcus may be primary, but is often secondary to pneumonia. The exudate into the pleura caused by the pneumococcus may be fibrinous, such as usually occurs in pneumonia; it is occasionally sero-fibrinous, but more frequently it is purulent. Pneumococcus is usually the cause of empyema in children, in many of whom no preceding pneumonia can be demonstrated.

Pleurisy is usually primary unless an interval of a day or more occurs after the defervescence of pneumonia before the symptoms and signs of pleural effusion set in; but there may be no interval, empyema beginning before the pneumonia ends, or the interval may be protracted even to several weeks.

Strepto-coccal pleurisy is a typical empyema of the adult. Infection may take place directly from the lung as from broncho-pneumonia, gangrene of the lung, pyemic abscess or tubercle; or from more distant parts, as from ulceration of the esophagus, abscess, caries of spine, etc. The germ may come from the blood in general diseases as septicemia, fevers, erysipelas, etc. Rheumatism and chronic Bright's disease are predisposing causes. If rheumatism is microbic, it simply means an extension of the disease to the pleura (and frequently pericardium).

In the case of chronic Bright's disease a certain proportion of them have been relegated to the tubercular pleurisies.

It is doubtless true that a chill or exposure to wet or an extension of some disease elsewhere, starts up a congestion and inflammation in the pleura; this condition may leave a good site for the tubercle bacilli later. Or the bacilli may be present with the other inflammation till long after the primary disease abates, or the tubercle bacilli may be the originating virus and be a tubercular pleurisy immediately. Yet a large percentage of cases of uncomplicated serous pleurisy are in good health for several years, at least after the attack. But many that are apparently well after two to five years develop tuberculosis later (fifteen per cent); in most of these cases, also, the disease being of a slow, rather mild type. But a very rapid tuberculosis may develop many years after the pleurisy, twenty years or more, so that the patient is never safe from the possibility of death from tuberculosis merely because his pleurisy lies ten, fifteen or twenty years behind him.

These pleurisies that are later followed by tuberculosis are, as a rule, the mild forms; they develop usually but one attack, and the fluid does not recur after tapping. Of course, the chronic form, which refills after tapping, is usually tubercular from the start.

But in spite of all this, many patients undoubtedly recover from pleurisy and die of affections in no way associated with tuberculosis, and at least, in a large percentage of those who are free from a tubercular family history, the ultimate prognosis is bright, with proper treatment. But in the hollow, narrow-chested and anemic, with doubtful family history, the prognosis is always doubtful, and in many cases the same precautionary treatment as in incipient tuberculosis should be instituted.

405 Syndicate Arcade.

For the enlargement and betterment of the *Oklahoma Medical News-Journal*, beginning with the January, 1907, issue, the *Oklahoma Medical News-Journal* will have a new editor, Y. E. Colville, B. S., M. D., of Chattanooga, Tenn. Dr. Colville has bought a half interest in the journal, and will devote his entire time to the editorial department, while Dr. Phelan will be the business manager. In this way the journal will be greatly benefited and enlarged, and will be more valuable to the profession than heretofore.

[Written for the MEDICAL BRIEF.]

Report of a Case of Puerperal Infection Treated by the Pryor Method.

BY C. K. FLEMING, M. D.,

Professor Gynecology and Abdominal Surgery Denver and Gross College of Medicine; Attending Gynecologist to Denver City and County Hospital and to Mercy, St. Joseph's and St. Luke's Hospitals. Denver, Colo.

Mrs. A., aged twenty-two; married ten months; primipara; confined the 25th of February. On the third day following she had a severe chill; temperature rose to one hundred and four; declined next morning, when it was followed by a slight rise for ten days. Temperature ranging from normal to one hundred and three or one hundred and four at night. She had been curetted following the first chill with no apparent benefit. Douches were given regularly, and the usual treatment was employed for puerperal infection.

I first saw her on March 6th, when she was brought to Mercy Hospital. Temperature at this time was one hundred and four, pulse one hundred and eight. Following her admission to the hospital she was sent to the operating room, examined, and thoroughly cleaned. It was found at this time that the uterus was six or eight inches in depth, the os patulous, and exuding from it was a purulent discharge. There was no tenderness or other sign of infection in the uterus or the pelvic cavity.

A complete laceration of the perineum was found which had been previously sutured, but suppuration had occurred, and it was necessary to remove the stitches in order to properly sterilize the parts. The uterus was irrigated with a fifty per cent solution of alcohol in water, and a drainage tube surrounded with iodoform gauze was placed to the fundus. Temperature next morning had dropped to one hundred and one and a half only. Pulse one hundred. The alcohol irrigation was repeated with no apparent result.

The symptoms continued about the same until the morning of the ninth, or the twelfth day following her confinement, when her temperature dropped to ninety-nine and a half, pulse remaining about a hundred. The next morning she was taken with a severe chill, temperature rising from one hundred to one hundred and five and three-quarters late in the afternoon, pulse still remaining in the neighborhood of one hundred. Her temperature dropped gradually, falling under uterine irrigation and removal of the packing and tube, and on the morning of the twelfth it was in the neighborhood of one hundred again. On the morning of the thirteenth her temperature was one hundred and one and three-quarters; during the day she had another chill, the temperature rising to one hundred and five and three-quarters again, dropping the following morning when another chill occurred, and the temperature again rose to one hundred and five and three-quarters.

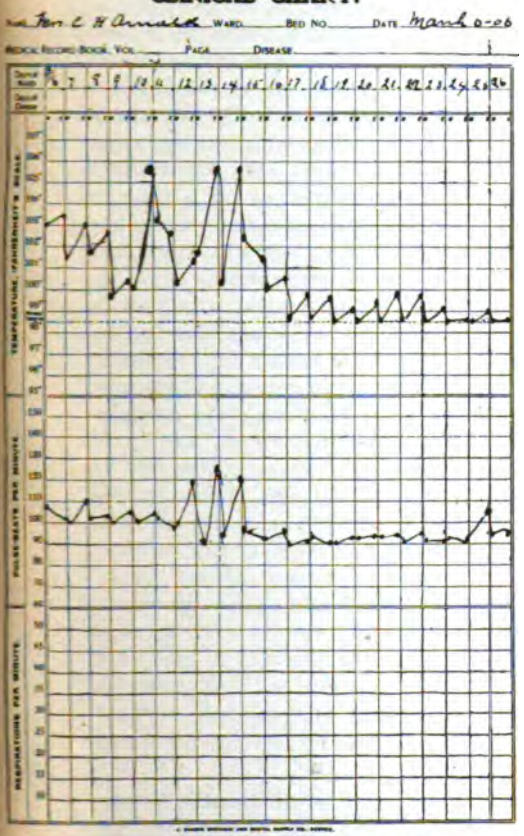
The patient appeared to be extremely ill, and it seemed that if anything was to be done to save her it should be done immediately. The question of hysterectomy was considered, and decided not feasible on account of the high mortality following such procedures in septic cases. After explaining the dangers of such an operation to her husband, it was deemed best before doing a radical operation to perform Pryor's operation, viz., the cul de sac incision and drainage.

During the past week she had received the usual treatment of forced nourishment, whiskey, strychnia, the subcutaneous salt solution and the use of streptolytic serum. The patient was properly prepared and sent to the operating room. An incision at least two inches in length was made into the cul de sac of Douglas. The peritoneum was found apparently healthy, and from the combined examination no involvement of the appendages was discovered.

In trying to incise the peritoneum we found that it was very readily detached from the uterus, so that it was stripped almost completely from its posterior wall. Although this was an accident, it impressed me as a valuable addition to the Pryor operation, for, from the denuded surface great quantities of serum exuded, during the succeeding forty-eight hours, thus depleting and draining the uterine tissues. Five per cent iodoform gauze

was packed carefully around the appendages and beneath the broad ligament; according to the directions of Pryor this gauze was allowed to remain for seven days. The morning following operation the temperature dropped to one hundred and two, and in three days it had reached normal, where it remained practically during the patient's convalescence. (See chart.)

CLINICAL CHART.



I believe this patient owes her life to the Pryor method. Had we performed a hysterectomy, as was first considered, it probably would have been fatal.

Puerperal fever is primarily a wound infection, therefore, a local disease. In its treatment we should follow the surgical principles which govern the treatment of infected wounds, viz., sterilization of the wound and drainage of the lymphatics.

In the majority of cases the uterine cavity can be sterilized by repeated uterine injections of antiseptic solutions, such as solutions of bichloride of mercury, etc. All abrasions of the vagina, tears of the cervix and perineum, if infected, should be cauterized with carbolic acid and alcohol.

Formerly results have been very good in similar cases where alcohol has been used in fifty per cent solution for irrigation of the uterine cavity, and in most cases will meet the indications; but there is a class of cases where the infection has traveled rapidly outside the uterus into the pelvic lymphatics, and it is in such cases that irrigation of the uterus will be of no service, and something more radical is necessary. In these cases some authors recommend hysterectomy, but I am firmly of the opinion that such patients will do much better by the Pryor method than by subjecting them to the more serious operation.

The Calciums.

BY S. R. GEISER, M. D.,

Professor of Materia Medica and Therapeutics in the Pulte Medical College; Attending Physician to the Bethesda Hospital and Consultant to the Protestant Home for the Friendless and Foundlings. Cincinnati, Ohio.

Therapeutics call for a method of treatent that has for its aim not alone the removal of symptoms, but the elimination of all the etiological factors entering into the production of the pathological lesions. It should also be our aim to remove the pathological lesions and bring about as nearly as possible a normal state in the organs implicated.

What constitutes a calcareous individual? A rational reply would be "one that needs lime." Would such a one be profited by filling him up with this solution? No, one who is by nature sick, one who is born so, born with an inability to digest the lime that is in his natural food, and consequently he grows large, fat but flabby, and in want of strength.

In looking for indications for a remedy we should not look for symptoms common or usual to other drugs, but rather for unusual symptoms; symptoms not be-

longing to other remedies. Of that class there are sufficient for reasonable results. I say for reasonable results, because we too often look for unreasonable ones from drugs, and overlook everything outside of the indicated remedy. On the other hand, we are oftentimes too willing to attribute unusual results entirely to the action of a drug. We should remember that all that can be expected of drugs in any disorder is that they remove obstructions and assist in bringing about a reaction, the cure to be left to nature.

A salient or leading symptom calling for lime is congestion, determination of blood to the head and to other parts, hot head but cold feet, but with these symptoms paleness of the parts, whether cold or hot. Calcium is often overlooked in some acute affections, as scarlet fever, measles and the like. To picture a calcium patient in our mind is not an easy matter.

It is said that as a rule calcium is of more service in the disorders peculiar to women and children rather than those of men, especially those of leucophlegmatic temperaments. Yet the rheumatism, gout and gastric disorders of men not infrequently call for calcium. The mentality of the calcaria carb. patient tends to melancholy, fear of becoming insane, poor memory, who is at the same time suspicious. The remedy will oftentimes establish a state of order, so that digestion and assimilation go on, the tissues are improved, and with them the mentality.

In treating mental disorders this drug is rarely thought of on account of the generally relaxed and flabby tissues; the woman flows too much and too often at the menstrual period. This great state of relaxation which we always find in calcaria carb patients is also manifested in leucorrhea and other catarrhal conditions. I have in mind a fat, flabby, nervous, suspicious individual, who, on account of excessive prolonged and frequent menstruation, had been advised to submit to curettement, who was entirely cured of this as well as of other unpleasant symptoms by the use of calcaria carb. While this woman was fleshy but flabby, she was anemic, pale, waxy, sickly, pale lips, pale fingers, in other words, she was chlorotic.

This was a case where we would usually think of iron, or, possibly, of the hemaboloids. This woman seemed ready to develop some malignant type of disease, other members of her family having gone that way. I am reasonably certain that health was restored to this woman and other similar ones by the persistent use of calcaria carb. rather infrequently prescribed.

It is a well known fact that calcium tends to attack glands, especially the lymphatics. Calcaria tends to resorb glands that are hard, sore and inflamed. Why is this? It is not yet completely known, but it is a fact, that if calcium is prescribed to a patient with a tuberculous tendency, for instance, the threatening disorder will be warded off for a time at least, provided the environment and other conditions be proper, nor will any other drug render as efficient service.

Again, the calcium patient is extremely sensitive to damp, raw winds, nor has he the mental ability to sustain any prolonged effort. This array of symptoms indicates that he is not assimilating the preparation of lime given in the food.

The respiratory organs furnish one of the best fields for calcium. It corresponds to just such constitutional weakness as is present in the first stage of tuberculosis. Calcium seems to at least suspend inflammatory conditions, and raises the condition of lowered vitality forces, and thereby dispels the tendency to take cold. Of course, a patient with tuberculosis will not be cured with calcium, nor any other remedy; it is in prevention lies our hope.

It is the remedy, pre-eminently, for partial sweats, as the nape of the neck, axilla, hands, knees and feet. In all these sweatings the surface is characteristically cold, especially the lower extremities.

In chronic sore throat I think that the calcaria carb. is too frequently overlooked. In persons who take cold easily and scarcely recover from one before acquiring another, calcium will assist in warding these off. These are but a few of the symptoms calling for the calciums, but they are sufficient to call attention to their importance.

The Groton.

[Written for the MEDICAL BRIEF.]

Vaginal Section.

BY BEN L. DORSEY, M. D.,
Professor Gynecology of Barnes University.
St. Louis, Mo.

Among the many maladies which are brought before us for consideration today, probably one of the most common, yet one which is fraught with danger, is that condition known as ventral hernia. Notwithstanding asepsis, technique, or the ability of any operator, the symptoms of hernia may become manifest not only months but even years after an abdominal section. The obsolete method of closing the abdomen with one single through-and-through suture has been the cause of bringing to our attention many of these unfortunate human beings. Even today, with the greater amount of knowledge which has been taught us by time and experience, we find the systematic closure of the abdomen by successive layers, viz., the edges of the peritoneum, the edges of the rectus and its sheaths, later the through-and-through silkworm gut, and finally the coaptation of the epidermis with horsehair or kangaroo tendon, the results are not what the surgeon might desire. Especially is this the case in that class of women who early arise from their beds, or commence their household duties too soon after operation. Even the abdominal supporter fails to perform its function. We have no means as yet of applying any contrivance which equals the natural support.

The vaginal route for operation offers us the only prophylactic when dealing with enlarged ovaries in size not larger than a hen egg; or in cases of tubal trouble, ectopic gestation, etc., where the growth is not larger than three inches in diameter. We are also able to remove, with comfort to the patient and satisfaction to the physician, fibroids of the uterus, where they are intraligamentous or of subperitoneal variety.

In many cases of pyosalpinx there is no means of removing the tube without any portion of its contents being distributed within the pelvic cavity while endeavoring to remove it through an abdominal incision. Again, we find a natural drain should be placed through the cul-de-sac of Douglas and out through the vagina.

We feel sure that had our knowledge in the past been equal to that of today many of our trusting patients would still be with us. We reflect with horror upon the great amount of danger done in our work by the use of the old glass vaginal drainage tube.

I often wonder if my fellow practitioners stop to consider the large doses of salines which were given in order to produce the necessary catharsis, when the real cause of the obstinacy of the bowels could have been determined by a consideration of the unnatural pressure which was placed in a very vital spot—commonly called the abdominal drain.

Vaginal section means much to those who are young and unmarried. An ovary may be removed, or a part of both ovaries, the tubes, or even small abdominal tumors, without the knowledge or the ability of anyone to determine later in life. This fact alone should cause us to be conservative and not produce unsightly scars, abdominal hernias and fistulous openings.

A cystic ovary which contains even a pint of fluid can easily be removed via the vagina. The pelvic cavity may be entered by an incision between the uterus and rectum. This vaginal incision should be made from one and one-half to two and one-half inches in length, and where necessary on one side an incision may be extended upward through the ligaments, ligating the uterine artery. Through this triangular opening the index or middle finger can be introduced, making it possible to palpate the pelvic organs on the affected side without danger to the uterus from lack of blood, owing to the supply of the opposite uterine artery.

Pelvic palpation may often determine a large ovarian cyst or hematosalpinx, pyosalpinx, hydrosalpinx, and even ectopic gestation, the size of which may be reduced by the use of a trocar. Especially is this true where the ovaries are cystic and contain a pint or more of fluid. When the contents of these escape

through the trocar there will be a collapse of the tubal walls, which may then be drawn through the vaginal orifice without any great danger to the patient. The stumps may be ligated, the abdominal parts removed, and after a moment's careful inspection, noting that there is no bleeding, they should again be returned within the pelvic wall. After inserting a sterilized rubber tube, or even a gauze drain, in the opening, the patient is placed in bed where recovery should rapidly follow.

Chronic Atrophic Gastritis.

BY SIMON P. SCHERER, M. D.,

Professor of Diseases of the Digestive System and Physical Diagnosis in the State College of Physicians and Surgeons. Indianapolis, Ind.

In our treatment of a disease so important as gastritis, it is of the utmost importance that we are positive of our diagnosis. There is no distinct condition of the stomach so often erroneously diagnosed as gastritis. Many dynamic affections are called gastritis, and it is a common practice for the patients to make their diagnosis and name their diseases "catarrh of the stomach." There are two pathological processes inseparable from every chronic gastritis. First, the hypertrophic variety with proliferation of the connective tissue, and in some cases cystic degeneration of the gastric tubules. Second, variety, the one which I wish to discuss, the atrophic form, whose pathological change is contraction of the connective tissue, loss of epithelium and partial or complete destruction of the gastric glands.

In making a diagnosis of atrophic gastritis it becomes necessary to exclude all other forms of stomach disease and to bar out the dynamic affections, many of which are confused with gastritis in some of its forms. In atrophic gastritis we are dealing with a distinctly anatomical disease, one whose mode of onset is as insidious as it is incurable. This form of gastritis is brought about by an aggregation of abuses and little accidents gone to seed. Usually this pathological condition is produced by poor food, improperly prepared and badly masticated; therefore atrophic gastritis is a disease frequently occurring in the poorer classes of shop and factory workers, living in bad quarters, and using coarse foods of poor quality, and very badly prepared, as a large percentage of the food consumed is only half-cooked.

The diagnosis of atrophic gastritis can only be made by the application of all the modern methods of diagnosis, for in this disease we have many symptoms foreign to the location of the pathological changes visible. For instance, we have anemia from subnutrition, kidney symptoms often occur as a result of intestinal indigestion, and an overworked liver; grave disturbances of motility, secretion and absorption; impaired motor power of the stomach, diminished quantity or absence of free hydrochloric acid and in the more severe cases complete achylia. Fermentation, belching, eructations, soreness of the entire stomach muscle, nausea, vomiting, first one symptom then another will appear then be entirely absent for a time, recurring after abuses of food and overexertion. One of the most constant symptoms is loss of appetite, although in some severe cases I have seen intense hunger and bulima, but after a full meal the patient usually vomits. This intense hunger is accounted for by subnutrition and reflex disturbance to the hunger center which is in the brain, instead of the stomach.

Physical appearance of the patient is usually one of cachexia, loss of weight, tired, haggard expression, stomach bulging forward, very tender, even the clothing becomes painful by pressing the stomach in any way. In the early stages we find free hydrochloric acid, but usually diminished. Later on, no free hydrochloric acid but a lower percentage of combined HCl, still later no secretion of hydrochloric acid, either free or combined is found and that proves complete atrophy of the gastric tubules verified by the absence of labzymogen. In the earlier stages we have constipation, but after the gastric glands have become atrophied severe diarrhea usually appears, due to the absence of proteolysis in the stomach and

the influence of irritating stomach contents thrown untransformed into an already insulted intestine. I have frequently relieved a diarrhea of several years' duration by the administration of dilute hydrochloric acid before and after meals. When albuminoids are reduced to peptone in the stomach, either by natural secretions or artificial means, the relief of diarrhea in these cases is usually assured. I found that during constipation associated with any form of gastritis that the use of resinous laxatives and castor oil is of greater importance than mercurials or saline laxatives. The latter, when administered in doses sufficiently large, often adds to the anemia already existing. When compensatory digestion by the intestine ceases we have paroxysms of diarrhea, which are often preceded by more or less severe duodenitis and catarrhal icterus, the so-called bilious spells of the old gastritis cases in which the stomach has failed to perform its function. The intestines are overworked, and irritating peptone gains access to the entero-hepatic circulation in large quantities until the epithelial cells in the liver are so overworked that they rebel, with the results above described.

In the more advanced cases with poor motor power and much retention of mucus, coated tongue, millions of bacteria are formed in the stomach from fermenting food, and gastric lavage is of great benefit to the patient, preferably used in the morning preceding breakfast, or at least four hours after the meals. I use lavage water containing two ounces to the pint of a saturated solution of salicylic acid, or a five per cent solution of dilute hydrochloric acid, which changes the flora of the stomach and disturbs the breeding grounds of fermentative and pathological micro-organisms. I have frequently increased the secretion of hydrochloric acid in the earlier stages of this disease by intra-gastric faradic electricity, using an Einhorn deglutible electrode, and Monell's high-tension faradic battery, with his dosage regulating device, making it possible to control the current to a nicety.

Of all diseases of the stomach where electricity is indicated, there is none in which the results are more pronounced, both in regard to secretion from the gastric tubules and increased motor power of the stomach muscle, than the use of faradic currents in atrophic gastritis. When the secretory function is almost destroyed, the patients have noticed marked benefit from intra-gastric electricity, and I have conclusively proven by test meal examinations that intra-gastric electricity does stimulate the secretion of hydrochloric acid, unless the gastric glands are completely atrophied.

In summing up my experience over a period of ten years of special work in gastro-intestinal diseases I conscientiously say that I believe there is no branch of internal medicine where the results of treatment are more satisfactory to the patient than the service rendered the cases of chronic gastritis, after a thorough and painstaking examination is made and a positive diagnosis assured. These cases are often turned away as incurable, and lead lives of misery, finally dying from cirrhosis of the stomach.

The dietetic treatment of gastritis, as in all other forms of stomach disease, is of very great importance, and should always be based on the chemistry and motility of the stomach, but space will not allow of its description here.

513 North Delaware Street.

[Written for the MEDICAL BRIEF.]

Dementia Paralytica.

BY T. C. BIDDLE, M. D.,

Professor of Mental Diseases in the Kansas Medical College; Superintendent of Topeka State Hospital.
Topeka, Kan.

It is difficult to treat satisfactorily a medical subject upon which a book might be written in the scope of a paper. Such a subject is dementia paralytica, and it is my purpose only to attempt to briefly scan the more prominent symptoms of a brain disease that is important to the general practitioner, because he is not infrequently called upon to treat the disease, especially in its incipiency. It is doubly important that the disease be diagnosed early, for the reason that only in the earliest stage can any benefit be expected from treatment.

Paralytica dementia suggests itself to me as being the best of several synonyms that are employed to express a pathological condition of the brain that is of increasing importance. I say increasing importance advisedly, because the disease is increasing in frequency. Suggestive of the fact of the great increase of the disease, I will state that ten years ago, during my connection with the Osawatomie Hospital for Insane, we rarely had more than five or six cases of the disease in the Hospital for Insane, at a given time; while in the Topeka Hospital we have had an average attendance of about twenty-five cases of paralytica dementia during the past two years.

The synonyms of the disease are paretic dementia, general paralysis of the insane, general paresis, or paresis.

Burr defines the disease as displaying slowly increasing mental impairment, disorders of muscular movements, gastric and other nervous crises, disturbance of the higher reflexes (inco-ordination) and mental and physical decay.

Paralytica dementia appears to be a disease that is associated with modern civilization, and is seen chiefly in America and Western Europe, and seems to bear a relation to the advanced civilization of those countries. Until recent years it was rarely recognized in women. At this time a few cases are found in females. Of the thirty-two cases admitted at the Topeka State Hospital during the past two years, four have been women, but two are now resident. It is a disease of middle life, a majority of the cases appearing in the decade between the thirty-fifth to forty-fifth years. Of the thirty-two cases admitted to our hospital during the past biennium, twenty-three are with the ages above given. A few cases appear in earlier life, and occasionally one appears in advanced years. Our youngest case admitted was thirty-one and the oldest fifty-three.

It is observed chiefly in persons of irregular habits who have been addicted to various excesses, who have had syphilis, alcohol habitues, and those who, from one cause or another, have exhausted nervous systems. Syphilis is the predominating cause of paresis. Some observers believe it to be an exclusive cause. I do not agree with this extreme view, yet I am in sympathy with those who regard syphilis as entering into the causation of at least seventy-five per cent of cases. Of our thirty-two cases, syphilitic history is elicited in only seven cases, or a percentage of twenty-two, but it must be considered that it is not always possible to elicit the syphilitic history when present. Some deny it wilfully, others are not conscious of its presence, while many are too demented to understand or express information correctly.

The disease is likely to attack persons of high-strung, nervous organization, intellectual men of affairs, actors, statesmen, professional men, those accustomed to working at high pressure.

Pathologically the disease is a meningo-encephalitis. No other brain or mental disease presents such pronounced pathology. There is degeneration of the cortex and a low grade of inflammation of the cortex and membranes. In advanced cases there is atrophy of the brain, the convolutions are shrunken, the sulci being filled with inflammatory debris. Adhesions of the pia mater to the cortex are found post-mortem, and the membranes are adhered to each other. The arteries and arterioles are contorted and friable.

Of the clinical history of the disease the symptoms may be divided into two classes, the physical and the mental. The mental disturbance is usually consistent with a state of exaltation, and change of the emotional state. In the early stage of the disease, change in the individual's character is observed. The careful, prudent business man becomes visionary and erratic, given to foolish speculative investments and the like. The steady man becomes unsettled and changeable. The individual of good habits becomes intemperate and given to licentiousness. The person of even temper becomes irritable and quarrelsome, especially if he is opposed in his unusual conduct and undertakings. In this early stage, his ideas are likely to be expansive in character, having large ideas of business, entertaining impracticable schemes, engaging in unwise investments, or dissipating his estate in extravagant

purchases. He becomes careless and indifferent in his affairs, neglects his duties, and is in every way unreliable. With the progress of the disease, the psychical changes become more pronounced; the expansive ideas develop into delusions of grandeur, in which the man believes he is possessed of great wealth, or that he is a person of great consequence, or perhaps his delusions are on the line of unlimited physical power. He owns all of the wealth of the world, or he is the strongest man of the age.

Patients suffering from paresis are rarely irritable unless opposed in their undertakings. They are governed in their conduct by a sense of well being. They are cheerful, happy and comfortable. Throughout the course of the disease, even into the lowest stages of dementia, they will answer inquiry concerning their health with the stereotyped phrase: "First rate." This, even when the motor disturbances scarcely enable them to utter the words. This expression is so characteristic of the disease that it has been called the "verbal formula of a hopeless malady."

Periods of furious and unreasoning excitement sometimes occur during the progress of the disease. These, as a rule, are of brief duration, in which the patient loses all self-control and is noisy and destructive.

Progressive mental deterioration is the most unvarying history of the disease, though rarely remissions in the progressive decline are observed. The remissions are only temporary in character to be followed by relapse and further mental decay. The deterioration progresses until, in the late stages, all mentality disappears and the patient lives merely a vegetable existence.

The developmental stage is, in a few cases, maniacal in character. I have seen several cases of paresis that were thought to be mania with all the psychical disturbances of mania present, and the physical signs of paresis obscure or not present. These cases, after subsidence of the stage of maniacal excitation, pursued a consistent history of dementia paralytica.

Again, there is an occasional case that is associated with depression. The depressive types are associated with most grotesque delusions of hypochondria, together with exaggerated depression, though the delusions of personal unworthiness, characteristic of melancholia, are not present.

One case of depressed type of paresis that died of fatal cerebral congestion, contended that his stomach had been changed to metal, and insisted upon an X-ray exposure in order that he might convince us that he was correct.

Of the physical signs, no other brain disease presents a sequence of symptoms that are so certainly diagnostic. In not all cases are the physical signs so perfectly marked, but where present they render the diagnosis a matter of little uncertainty. In many cases when advanced to full development, to hear the patient speak or observe his movements and facial expression, causes the experienced observer to intuitively recognize paralytica dementia, as you recognize a case of tabes.

Motor disturbances appear early, and consist first of fibrillary tremor, especially marked in the protruded tongue. The hands tremble, particularly when engaged in some complicated movement, like buttoning the clothes or writing. The writing of a paretic is quite characteristic. Muscular twitchings of the facial muscles are often present. Pupillary changes are the rule. These changes may be inequality of the pupils or sometimes dilatation of one or both, but more frequently the pupillary disturbance consists of immobile pin-hole contractions. The Argyll-Robertson pupil is often found.

With the development of the disease, the ataxic gait is present in almost all cases. Ataxia is not infrequently so pronounced as to render the man nearly incapable of locomotion, and closely resembles tabes. These cases are known as the tabetic type of paresis. The condition is doubtless due to involvement of the cord in the inflammatory change.

The most characteristic symptom of paresis, and the one that is the most pathognomonic, is that of speech disturbance. It consists of an indescribable indistinctness of articulation and slurring of words, in which letters and syllables are omitted. When associated with the peculiar starting and twitching movements of

the lips that is usually present, it is most suggestive of the disease.

More frequently exaggerated reflexes are found, yet often the opposite is present, with complete loss of reflex movement. Commonly there is changed facial expression, due to loss of nerve tension of the muscles, giving the face a characteristic expression, in which the natural lines and grooves of the face are absent. This is sometimes called the paretic mask.

The history of paralytica dementia is progressive; the case goes on from bad to worse, the symptoms becoming more pronounced with occasional periods of remission. At any time during the progress of the case seizures of an epileptiform or apoplectiform character occur. These seizures are the result of severe congestion of the brain or actual effusion of blood into the brain. A recent post-mortem in a case that had died suddenly in a fatal apoplectic attack, showed a large subdural hemorrhage. Congestive attacks may be fatal, but usually, under proper treatment, they recover from the attack, but with each recurrence the signs of the disease are more pronounced, and the patient declines into a lower grade of dementia and helplessness.

Of the differential diagnosis, alcoholic pseudo-paresis is the most difficult. Both the psychical and physical symptoms of true dementia paralytica may be present in pseudo-paresis. There is, however, a difference in the clinical history. In pseudo-paresis there is not the progressive decline, both mental and physical, that characterizes dementia paralytica.

The history of alcoholic excess will be suggestive of the type of disease. Not infrequently we can reach a correct diagnosis in the two conditions, only after protracted observation and study of the clinical history. It is sometimes difficult to determine where a case of depression is melancholia, or the depressed type of paresis. My experience leads me to believe that there are not many cases of depressed paresis; elation is the rule. The grotesque hypochondriacal delusions of paresis, together with the absence of delusions of personal unworthiness that are characteristic of melancholia, and the physical signs of paresis will enable us to complete the diagnosis.

The prognosis in paretic dementia is altogether unfavorable. The average duration is three to four years, some cases pursuing a rapid course to fatal termination in three to six months; others may live six to eight years. In the terminal stages they become helpless and bedridden, lose all control of the sphincters, and are most untidy and disgusting in their habits. Trophic disturbances appear in the course of the disease, rendering it necessary to exercise the greatest care to prevent bedsores. The bones become friable, and are sometimes broken as the result of surprisingly little force.

The prognosis suggests that little can be accomplished with treatment. The most satisfactory feature of the treatment is that of the congestive attacks, which consists in the heroic application of cold, large ice bags to the head, and ice or cold packs to reduce the temperature. Without the use of cold, a large percentage of these patients will die in congestive attacks.

The Care of Feeble and Premature Infants Without the Aid of An Incubator.

BY A. B. CATES, A. M., M. D.,

Professor of Obstetrics in the Medical Department of the University of Minnesota; Obstetrician to the Northwestern Hospital, Bethany Home, etc. Minneapolis, Minn.

The country practitioner is rarely prepared for the most modern treatment of the premature child. The Lion's incubator is too expensive to be within the reach of any except those in the largest cities; the chicken incubator is not wholly reliable and supplies air which is too warm for the infant to breathe. From a considerable experience I have finally decided that I can achieve the best results from what is known as a basket incubator.

An ordinary clothes basket is lined with a quilt and the premature infant is immediately placed therein after it has received an anointing of sweet oil. It

is wrapped in absorbent cotton. This is covered with a blanket, and the blanket is kept in place by means of a roller bandage. Hot water bottles are placed beneath the child and a bath thermometer underneath the coverings. The nurse can carefully watch this thermometer and, by changing the water in the bottles or rubber bags, easily maintain a temperature almost continuously between 85° and 90° F. This temperature should never be allowed to fall below 85° F. A few degrees above that will do no harm. An equable temperature can be maintained without the assistance of an extra caretaker. This method of maintaining artificial heat is really superior to the use of an incubator, in that the child breathes the pure fresh air of a well ventilated room in which the temperature does not rise above 76° F.

The care of the child during the weeks of prematurity requires experience and training. The child's temperature should be taken regularly by the rectum, and if it fall considerably below normal the indication is to increase the heat from the water bottles.

The feeding is most important. Wherever it is possible mother's milk should be drawn from the breast and the temperature of the milk be maintained by immersing the bulb of the breast pump in a cup of warm water. At first it is best to dilute the mother's milk by an equal quantity of a solution of sugar of milk. Where mother's milk can not be maintained, the best formula for the beginning of the nourishment of the child would be milk one teaspoonful, sugar of milk one-fourth teaspoonful, lime water one teaspoonful, a pinch of salt, and boiled water enough to make ten teaspoonfuls. This may be fed to the infant in feedings of two or three drachms every two hours at first; gradually the amount of this mixture at each feeding should be increased until by the end of four days it has reached one ounce, and by the end of one week one and one-half ounces. After this time, if the food agrees with the infant, the proportion of milk should be one-eighth. By the end of three weeks the proportion may be raised to one-sixth; by the end of four weeks one-fourth. With the premature or feeble infant artificially fed, it need not be expected that the original weight will be regained by the end of four weeks. With the fully developed child the original weight is usually regained by the end of two weeks. It will be found frequently that the child must be fed by means of a medicine dropper. The most satisfactory device is a small rubber tubing covering the pointed end of an ordinary medicine dropper. The milk mixture is drawn into this dropper and forced gently into the back of the mouth. The presence of the soft tubing and a certain small amount of the mixture will commonly cause the infant to make sucking movements and the liquid will be swallowed. This method is successful when the child would not take the breast, the bottle, or swallow the liquid placed in the mouth from the teaspoon. Sometimes the infant will not swallow at all, or it will vomit everything taken into the stomach. In these cases the most satisfactory way of tiding the child over this danger period is by means of gavage. A small, soft catheter is passed through the nose, down the pharynx and into the stomach. The fluid flows in from a glass funnel. This nourishment will frequently be maintained when any other form of feeding would be unsuccessful. Very frequently I have been obliged to resort to the use of salt solution by the bowel; commonly the infant will retain two ounces.

A premature child should not be bathed for weeks; it should be rubbed with oil every few days. The cotton or diaper should be watched closely and frequently changed—on account of the urine or feces.

Cyanosis is frequent and often calls for mild stimulation with a few drops of brandy or whisky; sometimes it is relieved by food alone. Convulsions, in my experience, are common. They may arise from traumatism, hemorrhage or pressure upon the nerve centers, or they may be due simply to indigestion and the pressure of gases in the intestines. Often the convulsions are diminished in number or cease altogether in consequence of the use of an enema or the passage of a rubber catheter into the bowel to allow the gases to escape.

The temperature of the basket should be gradually reduced as the weeks pass

until a temperature of 76° F. has been reached.

The tendency is to make the food of young infants too concentrated. Once the digestion is upset, then arise difficulties in securing proper alimentation. When modified milk proves unsatisfactory peptonization is exceedingly helpful. Frequently whey dilated fifty per cent answers admirably for a time. This may be gradually increased in strength until there is no dilution.

The mortality in premature children is likely to run as high as fifty per cent. Frequently development is very tardy and often very unsatisfactory. In recent years among my premature children, one has marked strabismus, another spastic paralysis, another is an idiot. Sometimes one is led almost to regret the great efforts put forth to save the infant's life. The question arises, what class of infants among the premature or feeble demands the treatment outlined. When a child has a temperature per rectum considerably below normal that is an indication. When the child's weight is below four pounds we have another very positive indication. When the child shows redness of the skin, a diminished amount of subcutaneous fat, the presence of a good deal of lanugo, and nails which do not project beyond the finger tips, these are additional indications for special care.

[Written for the MEDICAL BRIEF.]

Concerning Diagnosis of Typhoid Fever—Case Reports.

BY E. L. CHAMBLISS, M. D.,
Internal Medicine in the University of Kansas.
Kansas City, Mo.

If diagnosis is always correct, typhoid fever, like many other diseases in modern times, is apparently becoming more prevalent and recovery more common. These facts are not alone true, but still more surprising is the fact that the so-called different types of this fever are becoming dangerously numerous.

The busy practitioner, particularly the consultant, frequently becomes astonished at the combination of symptoms which are being dubbed typhoid fever—and treated as such—and when recovery has occurred after ten days or two weeks it is taken for granted that a typical case of typhoid has been met with and that perhaps internal medication has influenced its course. Such impressions no doubt are very dangerous to the public and surely mislead the practitioner and cause him to create false ideas as to the possibilities in the handling of typhoid fever. I have had people say to me on occasions when typhoid fever was suspected, "Doctor, if this should be typhoid you can stop it, can't you;" or, "When my cousin had typhoid, the doctor just gave her some medicine which stopped the whole thing in a week."

The doctor who leaves such an impression is a menace to the profession; he is either ignorant or he is a fake. He is injuring himself more than his profession, however, and he either has not brains enough to realize this, or he does it for financial reasons.

I realize that we do have to contend with different types of this fever and that there may be abortive cases and mild cases, and, too, I realize that the condition of the victim, powers of resistance, vitality, age, and other influences which may direct the course of the disease, must be taken into consideration, but I am forced to believe that there are more cases of mistaken diagnosis than of anomaly. The fact is that diagnosis is the only hope for the future internist. The surgeon and the specialist are rapidly absorbing the whole field of treatment, and if we will stop for a moment and reflect we may readily see that after the specialist has had his just apportionment of cases, there will be left for the internist only a very limited number of diseases to treat; and if we reflect a little further, we find that it is a conceded fact that drugs do not influence many of the remaining maladies. In addition to these facts the surgical field is constantly offering so many new opportunities that a man does not get sufficient practical experience before he dives into some specialty which means treatment, and the diagnosis must be overlooked after all.

The result is poor surgery, incompetent specialists, and a gradual lowering of the standards of the profession.

Now, when we have the "Widal reaction" for diagnosis, we should use the pathologist in all cases of suspected typhoid fever, and should get a positive reaction about the seventh day of the fever. This positive reaction means the power of the blood or serum or other body fluids from a typhoid patient to cause a clumping of a culture of well defined typhoid bacilli. The clumping will occur rapidly and completely, according to the virulency of the typhoid condition.

This test is certainly a very useful aid in the diagnosis, but it is not infallible. There are a limited number of cases of other diseases which will give the positive reaction; this agglutinating power of the blood does exist in other conditions than typhoid, and we do not know what the diseases are. It seems that no particular disease or class of diseases will give this positive reaction more uniformly than another, but the fact remains that a small percentage of cases other than typhoid do give a clumping, and this fact must always be taken into consideration.

In the case of T. C., aged eight years, the following conditions were existent:

History: Four months previously, suffered with acute otitis media on right side, with considerable inflammation of antrum, extending over a period of two or three weeks, during which time there were numerous exacerbations of temperature and so much tenderness over the mastoid that the aurist seriously contemplated the necessity of radical surgical procedure, but the trouble cleared up perfectly in due time. Six weeks previous to illness in question, patient received a severe laceration of the left ear in an accident to the extent of an incision completely through the skin and cartilage which had not entirely healed, but which was discharging slightly from the sloughing cartilage.

Patient first complained of present illness August 29.

The temperature fluctuated very materially, during the first three or four days between 101° F. and 103.6° F., without reference to regularity, during which time there was intense frontal headache, severe nosebleeds and a general appearance of an oncoming attack of typhoid fever. Negative result in both diazo and Widal tests, with a leucocytosis of 21,500 by the third day and 16,800 on the fifth.

On September 3, the temperature was normal at nine A. M., rising to 101.2° F. in the afternoon. Painful micturition, negative diazo, with large quantities of pus in the urine; intense pain in the left side of the abdomen and in the nephritic region, marked edema of the eyes, and severe nosebleed.

On September 4, the seventh day of the illness, the pathologist reported a positive Widal reaction, with a negative diazo and considerable pus and epithelium in the urine, with a pure culture of the typhoid bacillus. Micturition was painful, and a diagnosis was made of pyelitis due to the typhoid bacillus, or nephrotyphoid fever. For several days the temperature was regular in its morning and afternoon exacerbations, reaching 103.8° F. in the afternoons, but on the seventh of September the temperature was normal at nine A. M. and 99.6° F. at eight P. M., and for several days following, normal all day.

Diagnosis in this case was based entirely on the Widal reaction, but the leucocytosis was the most interesting feature of the blood examination, particularly when we recall the statement of Cabot that "Almost all local inflammatory processes have leucocytosis, while typhoid (uncomplicated) does not." So that when the leucocytosis of 21,000 was reported in the above cases we went to work to find the cause, and up to this time there had been no symptom of any kidney affection. No kidney pain, not even a cloudy urine, absolutely nothing; but two days later blood was discovered in the urine and later pus in large quantities.

Inflammation of the kidney, or the pelvis of the kidney, was the cause of the leucocytosis and the typhoid bacillus the supposed cause of such inflammation. But again after a day or two of remission the temperature shot up and ran along for several days irregularly, then another remission.

It was suggested to the pathologist that possibly the colon bacillus was the cause of the pyelitis and that the culture of

typhoid bacillus was a mistake. He then obtained a pure culture of the bacillus coli communis, but also recognized another bacillus, so-called paracolon, which closely resembled the typhoid bacillus, and which he had evidently mistaken for the typhoid bacillus, possibly para typhoid. These remissions and examinations continued several weeks until the temperature finally reached 105.4° F., and remained between 104° F. and 105° F. for several days; dropping to normal suddenly. So this primary diagnosis was entirely wrong, due to the Widal reaction. I could report some very interesting facts concerning this case, but it is foreign to our subject.

Again, I have on several occasions met with delayed Widal reaction in typhoid fever.

Case of N. S., aged twelve years; onset and course well marked. After repeated examinations of blood the positive Widal reaction was only obtained at the middle of the third week; and in case of E. B., aged nine years, Widal reaction negative after fourteenth day of fever; did not try again, as clinical symptoms were very positive and the diazo test was positive all through attack, as it was also in case of N. S.

In typhoid the diazo reaction of Ehrlich is very constant, and I agree with the statement made by Filatov that "this test always succeeds in typhoid, beginning from the fourth to the sixth day of the disease, and is persistent during the whole course of the fever." The absence of the diazo reaction during the acme of the disease is against typhoid, and, "If the reaction once disappears it appears in cases of relapse, but this test proves negative as soon as the temperature depends on complications." However, the diazo test is existent with other diseases and particularly so with miliary tuberculosis, so that its clinical value for diagnostic purposes when considered alone is not so great as the Widal blood test. The test is of great value, however, if considered with the careful study of the clinical history and symptoms. Now in the case of pyelitis reported above daily urinary examinations always gave a negative diazo reaction, while the blood gave a positive Widal on two occasions.

My remarks are more particularly directed to the mild cases of typhoid and the so-called abortive cases, since these are most confusing to the practitioner. The abortive typhoid fever usually starts off violently and runs along a typical course rather severe, when, by the tenth day, it terminates suddenly, the temperature falls to normal and all the symptoms which have been well marked suddenly subside.

These cases should be managed with tact. Every effort should be made to verify the diagnosis and then to teach people what is meant by an abortive case of typhoid. That it is a type of typhoid which is terminated earlier than the usual type, and that "abortive," under these circumstances, does not mean "capable of being aborted" by treatment, but that it would be aborted if let alone.

In a case, T. D., male, aged thirty years, onset of attack was virulent and typical, both Widal and diazo appeared positive on the sixth day of fever. Maximum temperature on seventh, eighth and ninth days from 103.5° F. to 104.5° F., gradually descending to normal by twelfth day. He was kept in bed one week longer on restricted diet, when he felt so well that it was utterly impossible to keep him there longer. This was a typical case of abortive typhoid fever, but on the other hand, in the case of M. N., male, aged twenty-five years, I have to report a similar onset with a positive diazo on the fifth day. Maximum temperature on afternoon of seventh day 103.2° F., which receded to normal by ninth day. Widal negative. Temperature continued normal at maximum, but slightly subnormal in mornings until twenty-first day; I was about to let him up, when suddenly the temperature ran up to 103° F., and he ran a rather typical course for three weeks, suffering one slight hemorrhage and recovering at the fourth week. During the intermission the tongue did not clear up and the patient did not appear to have recovered, and it was with fear and trembling that I was about to let him up when the relapse occurred. The

Widal appeared positive on the eighth day of the relapse.

I merely report these cases to bring to notice such atypical cases and to show the necessity of verifying our diagnosis in all cases by all possible means. Hare has reported such a course as that outlined in last case.

I have occasionally found a case, apparently not very sick, with a temperature of 99° F., in my office in the afternoon, and which persisted in reporting daily with a history of feeling quite well in the morning. I would search carefully for pulmonary tuberculosis and every other possible affection for a cause for the temperature, when after five or six days I succeeded in getting a positive Widal and diazo reaction, I have decided on a typhoid diagnosis. These cases are hard to treat, but it is extremely important to give them every care and attention, for such complications as hemorrhage, perforation are just as likely to occur as if the temperature were running high and the Peyer's patches and solitary follicles were involved. On the other hand the para-typhoid of Schott Muller "may run a course just the same as typhoid without any lesions in the intestinal glands, and under such circumstances as above described the danger to the patient would be very slight if he should not remain in bed."

Blood examinations then surely render diagnosis much more positive and should be resorted to. A differential clinical diagnosis is very essential. Symptomatology is of vast importance in the diagnosis of typhoid fever, and diagnosis is the whole thing. The internist is rapidly turning himself out of business so far as the administration of drugs is concerned and diagnosis must be his hobby. Diagnosis is the most important feature in the practice of medicine. Diagnosis *is* the practice of medicine. No drug or lot of drugs can influence the course of typhoid fever. There is no specific. There is absolutely nothing which will abort, retard or end a case of typhoid fever in its prescribed course. The serum treatment will likely be the light which is to shine in this direction. Symptomatic treatment and careful nursing is the whole thing, but careful nursing means more than is usually understood by that phrase. The principal duty of the nurse is the very one which most nurses neglect—watchfulness for complications and ability to recognize them in time to overcome them. We should instruct the nurse at each visit what to expect, what to look for, and what to do if such complications should appear.

The anomalous cases of typhoid fever are the puzzling ones, not only in the diagnosis but also in the prognosis of the course. We must remember the case in which the temperature drops to nearly normal and other prominent symptoms subside earlier than expected, and after too much indulgence in solid food ends fatally with collapse, or perforation. In these cases the Widal test is valuable in verifying the diagnosis. We might feel, without it, that perhaps we were wrong, and feeling so become negligent in our cautioning to the serious detriment of the patient. Again I believe the doctor is decidedly too prone to credit such a sudden subsidence of active symptoms to the use of certain drugs which the patient happens to be taking at the time of such changes. There is no drug which will shorten the course of typhoid fever, which is now known. Variation from the usual typical course is rather the rule than the exception, and in many instances it is the complication which causes the variation.

The early recognition of the complication is therefore of the utmost importance. While there is no drug which will affect the action of the typhoid bacillus, there are drugs with which we can combat the effects of the action of the other bacilli, and these, among them bacillus coli communis, should be handled with intelligence and care.

Early Recognition of Tuberculosis.

BY SIDNEY J. MEYERS, M. D.,
Professor Medicine and Clinical Medicine,
Louisville Medical College, Etc.
Louisville, Ky.

Probably no subject at the present time is occupying the minds of the general practitioner as well as the laity as is tuberculosis. Well-defined cases of this disease are easily recognized by the practitioner, or even diagnosed by the family before the patient is brought to the physician for treatment.

It should be our aim not only for the progress of medicine, but for the good of the patient, to make a diagnosis of tuberculosis at the earliest possible moment, for with early diagnosis we can expect to get some benefit from the treatment instituted. A great many cases present themselves simulating to a marked degree malarial infection on the one hand, and rheumatic intoxication on the other. The physician as a rule is lax in his methods of diagnosis, and these patients are sent from our offices with a snap diagnosis of one or both mentioned conditions. The early recognition of this condition is extremely difficult, but when one is suspicious that there may be a tubercular involvement, repeated examinations should be made, and I am satisfied that after many repeated careful investigations that some evidence of this infectious disease may be made manifest.

Probably one of the earliest diagnostic points is the finding in the lung of some small area wherein we find a râle. This area may be very small, upon percussion there may be absolutely no dullness, and at times, upon auscultation, the breathing will be perfectly normal. Whenever râles do occur within any given area in the chest walls, our suspicions should be aroused.

Accompanying this condition we would have a slight deviation from the normal in the temperature range. We would also have a corresponding acceleration of the pulse, and the same ratio maintained in the respiratory movement. Repeated examinations of the sputum should be made. I say repeated advisedly, because often as many as twenty or twenty-five bacteriological examinations have failed to disclose the tubercle bacilli, when upon the very next occasion we have found the secretions swarming with germs. It is important here to suggest to the patient that sputum be given for examination, and not secretion from the naso-pharynx, as so often provided the examining physician.

Another sign that should not be overlooked is that of emaciation. This loss of weight need not be very marked, yet any loss combined with the above symptoms should make our picture rather clear. Rheumatism may be ruled out after a sufficient time has elapsed, and after a thorough anti-rheumatic treatment has been instituted. Malaria in its many forms which may be confounded as above stated, should certainly be differentiated quickly and scientifically by the isolation in the blood of the plasmodium. Should cases giving the symptoms described not yield to either one of the above investigations, then we should certainly consider tuberculosis as the causation of this symptom complex.

If we are able to recognize tuberculosis in this stage, in the stage of invasion practically, we may benefit the patient to the greatest possible degree, but if we allow this condition of circumscribed râles, slight elevation of temperature, only a few more than normal respiratory movements, acceleration of pulse, and emaciation to escape us, then we have lost the golden opportunity of relieving this very distressing and prevalent condition. I may be criticised for being suspicious of tuberculosis in all cases simulating the condition described, and yet a diagnosis need not be made until we are thoroughly satisfied regarding the existing conditions.

I have purposely avoided giving cough as a symptom of tuberculosis, because I believe that this has less to do with the making of the diagnosis than any of the objective or subjective signs attributed to this disease, coming, as it does, in so many conditions, and from so many different causes.

What shall we do in the time that elapses from the presentation of the patient until the diagnosis is made? Shall we alarm the patient by our suspicions,

or shall we let him go on and jeopardize those who are about him? We must all appreciate the infectiousness of this disease, and it is therefore our duty not always to inform the patient himself, but certainly those who are near or associated with him. The same precautions should be taken in preventing the spread of the disease at this especial time as is taken even in the most virulent cases. The patient should be treated with placebos just as we palliate those afflicted with syphilis between the time of the primary sore and the secondary eruption.

What shall we do when the diagnosis is made? The first and utmost requisite is to gain the confidence of the patient, and this can only be gained by positive and undoubted statements from the physician himself, and these in turn can only be made after we have satisfied ourselves that tuberculosis is the disease. Much depends upon the social and financial condition of the patient as to the character of advice that he be given. I believe little is accomplished from treatment by drugs. Treatment by regime and climate is the only thing that offers any hope to the sufferer. The patient should be informed as to his liability of infecting others. He should be impressed with the gravity of the condition, and should be told of the effect that climate and environment have upon the disease, and should be advised to find himself a suitable locality. I notice that most patients in this incipient condition will hesitate before giving up their business, or before allowing their families to be taken away from them, and yet we should be master of the situation, and insist that now is the time or never.

Should circumstances prevent the following of our advice, we must then battle with the condition at home, and insist upon the open air treatment.

My only hope in writing this short article is to insist upon an early diagnosis of this disease, upon being suspicious of every case presenting itself to us with the symptoms described, insisting upon the newer methods of treatment in tuberculosis, and the discarding of medicines which hold out hope, but in reality mean absolutely nothing to the patient.

[Written for the MEDICAL BRIEF.]

Syphilis of the Ear.

CHARLES J. LIDIKAY, M. D.,

Clinical Professor of Ophthalmology in the Medical Department of the University of Kansas.
Kansas City, Kan.

The percentage of cases of ear affections due to syphilis is much smaller than of eye cases from the same cause.

A primary infection of the ear is very rare, only a few cases being recorded. We may have a chancre on any part of the external ear or at the mouth of the eustachian tube, the former being caused by direct contact, and the latter, usually, by infected instruments, particularly the eustachian catheter.

The majority of syphilitic ear cases occur in the secondary and tertiary stages, and any part of the external ear or canal may be affected; the external canal may be invaded by condylomata. These in turn may cause suppuration, involvement of neighboring glands, and finally deafness. This canal may also be affected by diffuse inflammation, with little swelling and characterized by severe pain and profuse discharge.

In syphilis of the middle ear the symptoms are very similar to those of other ear conditions not syphilitic. We may find acute catarrhal inflammation, purulent inflammation, or neuralgia of the middle ear.

In infants suffering from syphilitic disease of the nose and throat, we frequently find affections of the middle ear. The bones of the middle ear are probably more frequently affected when the trouble is syphilitic. There are no characteristic symptoms by which we can differentiate between specific and non-specific forms of these diseases. Of course, signs of specific lesions in other parts of the body would aid us in making a diagnosis. In the offspring of syphilitic parents we sometimes observe great, if not total, loss of hearing in a very short time, due to syphilis of the middle ear. This is most common in females. The pathological changes causing the symptoms are unknown, although several theories have been advanced. It is not a fatal disease,

hence there have been but few opportunities for *post-mortem* investigation. In most cases that have been examined the mucous membrane lining the middle ear cavities have been found hyperemic, and in some cases involvement of the periosteum and bone.

The onset of this disease is sudden. Pain is rarely present. Vertigo, headache and staggering gait are the most prominent symptoms.

Treatment of this condition is of no avail as a rule, but we should always give mercury and the iodides to the point of toleration. The treatment of the inflammatory conditions should be local and internal. Internally, mercury and the iodides; locally, the condition of the nose and throat should be looked after and placed in the best possible state of health. Before suppuration takes place I make local applications of cocaine to the internal opening of the eustachian tube and surrounding tissues for the purpose of shrinking them and relieving the congestion of the parts. This shrinkage of the tissues permits the entrance of air into the eustachian tube by means of the Politzer bag, and permits drainage of serous or other discharge from the ear. I then paint the tube and surrounding tissues with a solution of silver nitrate, ten grains to the ounce. If the case has advanced to the suppurative stage, my first object is free drainage. This, in my experience, is best acomplished by keeping the ear thoroughly flushed out with warm water. My rule is to order a fountain syringe hung two or three feet above the patient's head and have the warm water run through the affected ear every two to four hours, or as often as there is discomfort. There are always plugs of pus and shreds of mucus and debris that a patient can not remove in any other way. Small ear syringes are not successful in accomplishing this result. I am aware that some authorities advise the insertion of a strip of gauze up to the drum for purposes of drainage, but in the majority of cases I find if the ear is dressed but once a day by this method we usually find an ear full of pus, and that the patient has suffered more or less pain.

After two to four days of the hot-water treatment I find the discharge much thinner and less in amount. Pain and swelling are lessened, and we can then begin our antiseptic treatment. After the ear is thoroughly cleansed with a suitable antiseptic preparation, I thoroughly dry the canal with pledgets of cotton, and dust with an antiseptic powder, after which I apply a strip of gauze.

This dressing is repeated daily and then at less frequent intervals until the ear is well. If there should be ulcers or granulations, they can be touched with silver nitrate crystals or strong solution.

Hysterical Anesthesia.

BY B. T. ZIMMERMAN, M. D.,

Professor of the Principles and Practice of Medicine, Neurology and Clinical Medicine in the Louisville Medical College. Louisville, Ky.

Of all the sensory stigmata of hysteria the anesthesias are the most important and most interesting. This is due to the fact of the frequent occurrence of anesthesias and also to their objective nature. Hyperesthesia and parasthesia being signs which are for the most part subjective, and hence are not as valuable from the standpoint of diagnosis. The anesthesias affect both general and special sensation. The anesthesias of general sensation are usually the hemianesthesias, the geometric anesthesias and the irregular anesthesias. The hemianesthesia is the most frequent, the entire side of the body being affected, the anesthesias extending to the median line, both anteriorly and posteriorly, and there terminating abruptly, as a rule. Not infrequently we find special sensation diminished also on the anesthetic side, as, for instance, diminution of vision, or impairment of hearing.

The next in frequency is the geometric form in which an entire limb or portion of a limb is anesthetic, giving rise to the so-called "glove" and "stocking" anesthesia, etc. The rarest form is that in which

we find the anesthesia occurring in islets irregularly distributed over the surface of the body. These anesthesias are quite common in the entire paroxysmal state of hysterical nature, and a careful examination of the subjects of this type of the disease will be rewarded by the discovery of one of these forms of anesthesia.

This anesthesia is functional, and not organic; it is due to mental inhibition, and usually accompanied by other evidences of hysteria relative to the psychic sufferer.

It is very necessary that we be able to differentiate hysterical anesthesia from one due to organic lesions; there are certain evidences found in the former which are not seen in the latter type. The first and most singular of these is that the patient is unaware of the anesthesia until the condition is called to his attention by the examining physician. The entire side of the body may be anesthetic to pain, and yet the patient is apparently unconscious of the existence of this anesthesia. This, of course, is not true of anesthesia due to organic disease.

This anesthesia does not correspond with the anatomical distribution of the nerves. It is rather a physiological than an anatomical anesthesia; the line of demarcation between the anesthetic and the non-anesthetic is sharp in this respect; it differs from the anesthesia due to organic disease of the nervous system.

The third point is the changeability of the anesthesia and the anesthetic area can, by suggestion or by hysterical attack, or by the electrical current, become sensitive, and often is accompanied by the appearance of an anesthetic area on the opposite portion of the body.

It is important that the physician in searching for this form of anesthesia should not suggest the possibility of its presence to the patient, for the mere suggestion may be sufficient to cause an anesthesia. The examination then should be made without the patient's knowledge of the purpose thereof. Usually while the patient is conversing with the physician or an attendant, the mind being diverted from the process of examination, the best opportunity is offered. Not alone is general sensation affected, but the special sensation as well. The commonest form of anesthesia of special sensation is that of vision. Total blindness is uncommon; usually appears suddenly and disappears very readily. Very frequently, however, we find a contraction of the visual field. This may be very pronounced without causing the patient the least inconvenience. The contraction of the visual field from organic disease sufficient to produce marked interference with vision would cause no subjective symptoms in a case of hysterical contraction of equal degree.

Anesthesia of the auditory nerve is also met with; sometimes total deafness is observed, although this is extremely rare. The trouble in the special anesthesias seems to be central. The olfactory and gustatory nerves are also involved, giving rise to perversion of the senses of smell and of taste. These perversions do not cause disagreeable sensations, but rather pleasant ones, so that odors and flavors that are disagreeabl the attendants may be entirely agreeable to the patient himself.

The subject of hysterical anesthesia often becomes one of very great importance to the general practitioner because of its constancy in the severe forms of hysteria, and because of its value as a diagnostic aid.

Ligatureless Method of Vaginal Hysterectomy.

BY H. HUGH HELBING, M. D.,

Professor of Gynecology and Abdominal Surgery in the American Medical College.
St. Louis, Mo.

The operation differs from the ordinary vaginal hysterectomy in that the uterus is peeled out, as it were, pushing off the anastomotic artery, and thereby avoiding severance of the uterine or the anastomotic artery.

The operation is performed with the patient in the dorsal position, cervix being grasped with volsellum forceps; incisions are made in the cervix beginning about one inch distant from the cervical outlet anteriorly first, and then poste-

hence there have been but few opportunities for *post-mortem* investigation. In most cases that have been examined the mucous membrane lining the middle ear cavities have been found hyperemic, and in some cases involvement of the periosteum and bone.

The onset of this disease is sudden. Pain is rarely present. Vertigo, headache and staggering gait are the most prominent symptoms.

Treatment of this condition is of no avail as a rule, but we should always give mercury and the iodides to the point of toleration. The treatment of the inflammatory conditions should be local and internal. Internally, mercury and the iodides; locally, the condition of the nose and throat should be looked after and placed in the best possible state of health. Before suppuration takes place I make local applications of cocaine to the internal opening of the eustachian tube and surrounding tissues for the purpose of shrinking them and relieving the congestion of the parts. This shrinkage of the tissues permits the entrance of air into the eustachian tube by means of the Politzer bag, and permits drainage of serous or other discharge from the ear. I then paint the tube and surrounding tissues with a solution of silver nitrate, ten grains to the ounce. If the case has advanced to the suppurative stage, my first object is free drainage. This, in my experience, is best acomplished by keeping the ear thoroughly flushed out with warm water. My rule is to order a fountain syringe hung two or three feet above the patient's head and have the warm water run through the affected ear every two to four hours, or as often as there is discomfort. There are always plugs of pus and shreds of mucus and debris that a patient can not remove in any other way. Small ear syringes are not successful in accomplishing this result. I am aware that some authorities advise the insertion of a strip of gauze up to the drum for purposes of drainage, but in the majority of cases I find if the ear is dressed but once a day by this method we usually find an ear full of pus, and that the patient has suffered more or less pain.

After two to four days of the hot-water treatment I find the discharge much thinner and less in amount. Pain and swelling are lessened, and we can then begin our antiseptic treatment. After the ear is thoroughly cleansed with a suitable antiseptic preparation, I thoroughly dry the canal with pledgets of cotton, and dust with an antiseptic powder, after which I apply a strip of gauze.

This dressing is repeated daily and then at less frequent intervals until the ear is well. If there should be ulcers or granulations, they can be touched with silver nitrate crystals or strong solution.

Hysterical Anesthesia.

BY B. T. ZIMMERMAN, M. D.,

Professor of the Principles and Practice of Medicine, Neurology and Clinical Medicine in the Louisville Medical College. Louisville, Ky.

Of all the sensory stigmata of hysteria the anesthesias are the most important and most interesting. This is due to the fact of the frequent occurrence of anesthesias and also to their objective nature. Hyperesthesia and parasthesia being signs which are for the most part subjective, and hence are not as valuable from the standpoint of diagnosis. The anesthesias affect both general and special sensation. The anesthesias of general sensation are usually the hemianesthesias, the geometric anesthesias and the irregular anesthesias. The hemianesthesia is the most frequent, the entire side of the body being affected, the anesthesias extending to the median line, both anteriorly and posteriorly, and there terminating abruptly, as a rule. Not infrequently we find special sensation diminished also on the anesthetic side, as, for instance, diminution of vision, or impairment of hearing.

The next in frequency is the geometric form in which an entire limb or portion of a limb is anesthetic, giving rise to the so-called "glove" and "stocking" anesthesia, etc. The rarest form is that in which

we find the anesthesia occurring in islets irregularly distributed over the surface of the body. These anesthesias are quite common in the entire paroxysmal state of hysterical nature, and a careful examination of the subjects of this type of the disease will be rewarded by the discovery of one of these forms of anesthesia.

This anesthesia is functional, and not organic; it is due to mental inhibition, and usually accompanied by other evidences of hysteria relative to the psychic sufferer.

It is very necessary that we be able to differentiate hysterical anesthesia from one due to organic lesions; there are certain evidences found in the former which are not seen in the latter type. The first and most singular of these is that the patient is unaware of the anesthesia until the condition is called to his attention by the examining physician. The entire side of the body may be anesthetic to pain, and yet the patient is apparently unconscious of the existence of this anesthesia. This, of course, is not true of anesthesia due to organic disease.

This anesthesia does not correspond with the anatomical distribution of the nerves. It is rather a physiological than an anatomical anesthesia; the line of demarcation between the anesthetic and the non-anesthetic is sharp in this respect; it differs from the anesthesia due to organic disease of the nervous system.

The third point is the changeability of the anesthesia and the anesthetic area can, by suggestion or by hysterical attack, or by the electrical current, become sensitive, and often is accompanied by the appearance of an anesthetic area on the opposite portion of the body.

It is important that the physician in searching for this form of anesthesia should not suggest the possibility of its presence to the patient, for the mere suggestion may be sufficient to cause an anesthesia. The examination then should be made without the patient's knowledge of the purpose thereof. Usually while the patient is conversing with the physician or an attendant, the mind being diverted from the process of examination, the best opportunity is offered. Not alone is general sensation affected, but the special sensation as well. The commonest form of anesthesia of special sensation is that of vision. Total blindness is uncommon; usually appears suddenly and disappears very readily. Very frequently, however, we find a contraction of the visual field. This may be very pronounced without causing the patient the least inconvenience. The contraction of the visual field from organic disease sufficient to produce marked interference with vision would cause no subjective symptoms in a case of hysterical contraction of equal degree.

Anesthesia of the auditory nerve is also met with; sometimes total deafness is observed, although this is extremely rare. The trouble in the special anesthesias seems to be central. The olfactory and gustatory nerves are also involved, giving rise to perversion of the senses of smell and of taste. These perversions do not cause disagreeable sensations, but rather pleasant ones, so that odors and flavors that are disagreeabl the attendants may be entirely agreeable to the patient himself.

The subject of hysterical anesthesia often becomes one of very great importance to the general practitioner because of its constancy in the severe forms of hysteria, and because of its value as a diagnostic aid.

Ligatureless Method of Vaginal Hysterectomy.

BY H. HUGH HELBING, M. D.,

Professor of Gynecology and Abdominal Surgery in the American Medical College.
St. Louis, Mo.

The operation differs from the ordinary vaginal hysterectomy in that the uterus is peeled out, as it were, pushing off the anastomotic artery, and thereby avoiding severance of the uterine or the anastomotic artery.

The operation is performed with the patient in the dorsal position, cervix being grasped with volsellum forceps; incisions are made in the cervix beginning about one inch distant from the cervical outlet anteriorly first, and then poste-

riorly, and with fingers and spud working up along the anterior and posterior wall of the cervix until we reach a point at about the junction of the cervix with the body, where we will enter the pelvic cavity; first, anteriorly, then introducing the fingers and grasping the body of the uterus, it is tipped forward and pulled down into the vaginal canal. The index finger is introduced beyond the broad ligament, and with scissors incisions are made just outside of the anastomotic artery, or between this artery and the body of the uterus, until we have severed the connection of the broad ligament to the uterus. We then operate likewise upon the opposite side.

Should it be necessary to remove the ovaries as well as the uterus, after introducing the fingers in the peritoneal cavity, through the opening in the vesico-uterine ligament, we bring down the ovary and ligate the pedicle produced by pulling down the ovary, removing one or both ovaries by this method.

We find by operating in this manner that only small branches of the anastomotic artery are severed and require only grasping with the hemostat. That is, it is not necessary to use ligatures to stop the bleeding, but merely grasping these small vessels with hemostats and twisting them will stop the bleeding; thus we eliminate the element of shock from hemorrhage, and the patient recovers speedily.

The only distress produced is that caused from the anesthesia. Most patients will recover and be able to leave the bed in ten days to two weeks and will be out of the hospital in three weeks. This is quite a contrast to those patients who are operated by the abdominal route, and quite an improvement over the method of operating and dividing the uterine or anastomotic artery,

In cases where this artery is severed there is always danger of secondary hemorrhage, while in the method described above there is no danger of such a complication.

The Early Diagnosis and Symptoms of Consumption — Arguments Drawn Therefrom for the Subcutaneous Injections of Oil.

BY THOS. BASSETT KEYES, M. D.,
Chicago, Ill.

The diagnosis of consumption should be based upon its symptoms, and not from tests as to the reaction of the system, for that is sometimes deceivable, while the symptoms plainly point out the course of treatment and ways of living which the patient should adopt. An old tubercular lesion may remain dormant and not cause the patient the least annoyance, or interfere with his health, providing he is living a proper life as to matters of food; indeed, by this means alone, through some change in the life of a tubercular person, as an occupation which has increased his appetite, or through change of diet, the disease has been cured.

While the tuberculin test has been usually advocated only in the early stage of the disease, where the symptoms are obscure, I do not remember it, for the reason that it very often produces in these cases more than a slight fever, and, in addition, may produce chills and general malaise and aggravation of the symptoms, which, lasting for some days, weakens the patient, takes away his scanty appetite, so that from the test he has often lost in weight and, as a consequence of all the conditions enumerated, has lessened, rather than strengthened, his chance of recovery.

That early diagnosis of consumption is so important has been the excuse of the stanchest advocates of the tuberculin test, but I take it that the pretubercular symptoms, which should cause alarm, are so prominent that they can not fail to be recognized, and were treatment began at this time it would be more as a preventive measure. But it is only too often that the consumptive patient does not seek aid in the early stage, or his physician, recognizing the disease, has spared him of the knowledge, sometimes the physician himself being at fault, if he has allowed the disease to advance. Though understanding human nature, we

know that some of these patients do not follow the advice in the manner in which they should; again, how many have made a proper study of this disease, and are able to plan a diet disguising the large amounts of butter and fats, so as to be relished by the patient, and which are so essential to the cure of this disease, together with other articles of diet which, by their mechanical action, aid in the digestion of these fats?

In the diagnosis of early tuberculosis we must first consider the following points as aids:

1. The appearance of phosphate in the urine.

Phosphatic absorption and fat assimilation are closely connected, so much so that when hogs are fed upon a milk diet, in which all fats are eliminated, so far as practicable, phosphaturia develops. The consumptive patient, passing large amounts of phosphates in his urine, is cured of these symptoms by the subcutaneous injections of oil, and it is evident that the assimilation of the oil produces conditions for the greater absorption and assimilation of the phosphatic salts.

2. Loss of appetite, some indigestion, and a dislike for fatty foods, anorexia, and nausea, with progressive loss of weight, inequality and dilatation of the pupil.

Such symptoms call for outdoor life and forced diet.

3. Sleep sweats, general relaxation of the system, and a tendency to sweat from slight exertion, with a rise of temperature in the afternoon, then morning expectoration and cough, perhaps pain in the affected lungs, or in the supraorbital region and neck, and sometimes hemorrhage.

These symptoms call for subcutaneous injections of oil, for by their use we strengthen the patient by building up nutrition, and we furnish material for maintaining the normal heat of the body. Nature, being thus supplied, does not seek to conserve and save her forces and fat tissues from too rapid oxidation, by cooling the body with perspiration at the expense of the vitality and force of the body. On the contrary, the substance for oxidation and care of diseased tissues is furnished by the oil injected, as well as the substance for furnishing force and vitality to the body.

4. The period of invasion of the germ is commonly marked by symptoms of a chronic bronchitis, without pulmonary signs.

The symptoms which we have enumerated are premonitory, after deposit of the germs; when these are being thrown off, with consequent symptoms, the diagnosis is easy, but in the treatment of this disease we should not wait for advanced symptoms before beginning the treatment. The symptoms of cough advance with the amount and extent of inflammation of the lung tissue, and the sensitiveness of the throat, and the amount of anemic, blood pressure, and cardiac disturbances. When all of these symptoms have arrived, coupled with loss of weight, it is not necessary to confirm our diagnosis by finding of the germ. The general physical appearance of our patient, together with the symptoms, enable us to base our diagnosis.

Without entering upon the differential signs of this disease, we may mention signs of the diseases which have been said to be often confounded with tuberculosis, and from which differential symptoms should be kept in mind.

Chronic bronchitis, chronic streptococcic, or influenzal pneumonia, and syphilis of the lung, are among the inflammatory diseases of the lung which bear closest resemblance to tuberculosis. But when symptoms of wasting disease of a chronic type are present, with or without severe pulmonary symptoms, they call for, as the principal part of their treatment, nutrition, and this is best given by subcutaneous injections of oil. The same as to treatment can be said of these other diseases which may be mentioned as having symptoms similar to those of early tuberculosis, such as pernicious anemia, leukemia and pseudo-leukemia, but which require differential diagnosis; not on account of treatment so much as for the satisfaction of the patient and physician. As the symptoms of tuberculosis advance, all of the premonitory symptoms increase in severity and give rise to certain signs, characteristic of pathological conditions, which varies according to the form of disease and the resistance of the body,

depending upon the manner of the patient's living. The morning cough increases on account of the larger amount of inflammatory matter cast off from the lungs. The germ is now usually easy to find.

The symptoms of tuberculosis are now so prominent that they should be used to mark the stage of the disease rather than its diagnosis. The advanced pathological conditions, such as extensive inflamed bronchial tubes and lung tissue, with its crepitant and various râles, the consolidation and formation of fibrous tissue, with contraction and depression of the chest walls, with lack of cell and bronchial breathing, with various changes in the percussion note; the formation of cavities, with their various resonance, whistling, and râles, are all too evident of their pathological conditions to require description of symptoms here, for the reason that they indicate the stage of the disease, rather than its early diagnosis.

The thin, emaciated patient, with advanced disease, would never have suffered from the severe symptoms had subcutaneous injections of oil been instituted early in the disease. But there is still hope for those advanced in the disease, for by this method of treatment I have had patients recover from well-formed cavities in the third stage of the disease, and resume their occupation after six months' treatment, when they had previously been unable to work for one or two years, and, as we shall see in our lecture on pathology, subcutaneous injections meet every symptom and indication for the cure of the disease and all its pathological conditions.

Medical Wonders and Medical Blunders—A Story of Facts.

BY M. J. RODERMUND, M. D.,
Milwaukee, Wis.

CHAPTER XXIII.

Not having time to write the regular article intended for this issue, I snatch a few moments time to call attention to a subject that ought to be of interest to physicians during the coming months. About two months ago, in conversation with a few gentlemen, I called attention to present existing atmospheric conditions, and that if these conditions continue for several months we would hear of small-pox breaking out in this State, in certain territories, before December 1. I also stated that we would hear of small-pox first along the coasts of the Great Lakes, and that it would break out among the robust and hard-working men first. In the past two weeks several cases of small-pox have appeared along the shores of Lake Michigan and Lake Superior. As usual, the public are greatly frightened, and there will be the usual harvest of vaccination and quarantine enforced by the physicians. Near Lake Superior nine cases of small-pox broke out in a camp in three days. Where these nine strong men caught the small-pox, of course, is not mentioned, but it is strongly mentioned that a strict quarantine has been established, combined with vaccination, to prevent the spread of the disease.

If the present atmospheric conditions keep up we will find that small-pox will spread as usual, and that no health officer or doctor, by the present methods or any other method (excepting one), will prevent a single case of small-pox, but when the conditions that are the exciting causes change, the epidemic disappears. Why is this always the case? If the epidemic disappears on account of the methods adopted and enforced by the health board, then why would it not be the logical conclusion to blame the health officers to allow these epidemics to come back at their usual intervals? If they can stop an epidemic when it exists, why would it not be much easier for them to prevent an epidemic? Does not their own logic condemn them? To illustrate the principle I refer to more strongly, I will here describe the incident that created such a sensation all over the United States in January, 1901, and will clearly show that I knew what I was about when I selected this particular case. This lady had come to visit friends at Appleton from Shawano, about forty miles distant, and there had been no case of small-pox known within thirty to fifty miles of Appleton up to that time.

The articles published throughout the United States by the newspapers and magazines at the time, contained some truth,

but the whole truth has never been published. If the readers will pardon me for taking up space in the BRIEF at this late date, I will give them the facts just as they occurred, and nothing but the facts, and if it does not set you a-thinking, the rusty gearing of your cerebrum is beyond motion or activity.

On Monday, January 21, 1901, about 11:30 A. M., I entered the residence of Mr. F., where Miss Stark was confined and quarantined with small-pox. As I entered the house Mr. F. jumped up from his chair and said: "We are not allowed to let any one enter this house." "Never mind," I said, "I am not anybody, so perhaps you have made no mistake." I then stated that I came to see the small-pox patient. "There she is," he said, pointing towards a young woman in a far corner of the room. Mrs. F. sat by the window sewing, while a child about two years old ran about the room. There were, therefore, four persons in the same room. "Are you not afraid of taking the small-pox from the girl?" I asked. "No," replied the mother; "we are not afraid." "But the doctors say that this disease is very contagious, and are they not very careless and negligent in not keeping this patient away from the rest of the family? This looks as though the physicians do not care if the disease does spread, or that they do not believe it is contagious. In either case they would be rascals. This is a genuine case of small-pox, just see the large pustules, full of pus; of course," I added, "I know you can't take the disease from this young lady."

Then to show them that this was true, I broke open a large number, perhaps a hundred, of the large pustules on her face and arms, took the pus out of them and smeared it over my hands, face, beard and clothes, and, at the same time, remarked that I would now go home, only two blocks distant, to dinner. I made no mention of the affair to my family during the two hours I remained with them. From my home I went directly to my office without telling anyone. The first person who came in the office was an old friend, Rev. T., who has a parish at North Milwaukee. We shook hands heartily; in fact, I had entirely forgotten that I was covered with small-pox virus. I presented him with one of my books and, according to our scientific knowledge, I must have covered the book and gentleman with small-pox germs, and he, in return, must have exposed many people in Appleton, those he met on the train and, finally, his whole congregation. The germs on the book, I presume, are still enjoying themselves in the spiritual home of the reverend gentleman.

During the same afternoon I touched and handled the faces of several persons in my office, while treating their eyes, fitting glasses, etc. From four to six, and from eight to ten o'clock the same afternoon, I was at the Business Men's Club, where I mingled and played cards with the members. At the club in the evening the conversation drifted to the newspaper article that evening containing the notice of a case of small-pox being in the city, which, of course, was the same case I had visited in the morning. After discussing the subject for awhile, one of them asked me if I would visit a small-pox patient and then go home to my family. I quietly remarked that I would just as soon do it as visit a patient with a common cold. Finally, Mr. D., cashier in one of the banks at Appleton, remarked rather sarcastically, "Now, doctor, what's the use of talking such nonsense; you would no more think of visiting a small-pox patient and then go home with your family than you would go home and shoot one of your children. You are too sensible a man for that!"

The reader can imagine the state of my mind at that time, as none of them had an inkling that I was at that very time covered with small-pox pus, and that the cards we were playing with were being loaded with this poison. Still, I never once mentioned my visit to them. Further, I would never have gone to the club rooms if I had had the least idea that my actions would ever become known, as I knew the sentiment of these gentlemen, and I also had too much respect for them and myself to impose upon their feelings, even if I did know their belief was a foolish superstition. I have done similar acts dozens of times during the past fifteen years and have, in each instance, watched the results, and not the

slightest harm has ever been done to anyone.

To return to our subject. After leaving the club rooms that evening I went home, slept with my family, and the next morning took the train to Green Bay. I took breakfast at Green Bay, and then went to the store of Mr. M., who had engaged me to fit glasses for his customers on that day. I handled the faces of twenty-seven persons during the day, besides those I exposed on the streets and in the train on my way home. The next morning (Wednesday) when I arrived at my office I found several reporters waiting to ascertain if the report was true that I had visited the small-pox patient, and had smeared myself with pus. In the beginning I neither affirmed nor denied the accusation, because I did not want it known, but upon inquiry I learned that one of the neighbors had seen me come out of the house and had asked the health officer if the family had changed doctors, as she had seen Dr. Rodermund come out of the house on Monday. Consequently, there was nothing for me to do save tell the exact truth, in such a way as to mislead the public and to discredit me. Among other things they stated that I had personally bragged of what I had done, when they knew that I never intended it to become known to the world until the people were ready to consider such revolutionary truths for their own benefit.

I was allowed my freedom about the city all day Wednesday, but on Thursday, the fourth day, I was quarantined, and a guard of policemen stationed around the house. The people had been so aroused by the health officer, doctors, city officials, and the newspapers, that one of the policemen told me that it was a good thing I was protected by a strong guard, otherwise my life would be in danger. Saturday evening I broke quarantine, in spite of five policemen and the fact that the Mayor of Appleton, in a public meeting, stated that they had Dr. Rodermund bottled up as effectually as they had Cervera at San Diego; drove forty miles to Waupaca, took the train to Chicago, and had breakfast at the Great Northern. From Chicago I went to Terre Haute, Ind., and on my way back home I traveled and stopped off a half day or so at five cities in Illinois, but on arriving at Milwaukee I was arrested and held for four days in the pest house. This is, in brief, an outline of the whole episode which created such a sensation.

The policemen, doctors and health officers in the States of Wisconsin, Indiana and Illinois tried in every way, shape and manner, to trace a case of small-pox, but with no avail. Even after I had exposed five hundred thousand people and rubbed my pus-covered hands over thirty-seven faces, they could find nothing against me. Yes, if I had rubbed the pus of small-pox patients upon the naked body of every citizen in the United States, not a single case of small-pox could have developed. This is an absolute natural truth that can never be overthrown. My reason for this I have explained in previous articles the past few months in the BRIEF. Why is it that not a single physician of the forty thousand readers of the BRIEF will discuss or defend their present nonsensical, inhuman and brutal methods? I think there is only one point in this article, and it is this: If any of the thirty-seven people or myself would have taken small-pox it would certainly have been by infection (direct contact) and not contagion. If the disease can not be spread by infection there surely can be no danger in going into a room where a small-pox patient lies. The cause of small-pox itself can only be better proof, and this has been explained in former chapters.

(To be continued.)

330 Harmon Street.

[Written for the MEDICAL BRIEF.]

The Influence of Trifles.

BY S. E. GIBBS, M. D.,

New York City.

"For want of a nail the shoe was lost,
For want of a shoe the horse was lost,
For want of a horse the rider was lost,
For want of a rider the battle was lost."

And all for the want of such a *trifle* as a small nail, worth about half a cent.

But, of course, the *other side won*, and so it frequently happens in the practice of medicine.

How often do we find ourselves supplanted by some other doctor (perhaps in our estimation an ignoramus), and thus

lose a good family of patients whom we have for years felt that we owned, body, soul and pocketbook, for want of such trifles as a little tact, a little foresight, a word inaptly spoken, a wink, or a smile, just at the wrong time, or a sober look when we were expected to smile, perhaps at a silly joke, the point of which we did not discern till the next week. And we sit in our office and wonder why the family changed doctors, just when we were trying so hard to pay our last year's taxes.

I once met in consultation a most estimable physician, a man who had probably forgotten more about medicine than I ever knew. The patient was a wealthy old gentleman suffering from the effects of a cerebral hemorrhage, and was unconscious. Weeping friends surrounded the bed, expecting every moment to have the burden of his vast wealth saddled upon their shoulders. While waiting for the doctor's arrival some friends had administered a spoonful of brandy to the patient. My conferee detected the odor on the patient's breath, glanced at the bottle on the table, winked at me, and said: "That accounts for it." Instantly the anxious friends were aroused. "He never drinks," they indignantly exclaimed in chorus, and the consultant's prestige vanished like the morning mist on the mountain top. They never paid his fee.

Some years ago I visited a patient and received the congratulations of the entire family on his rapid recovery. They were *so grateful*, informed me that I had saved his life, and all that sort of thing which we so often hear. On passing through the hall I noticed a small, but exceedingly beautiful, painting, and remarked on its beauty. Fatal remark! All my skillful efforts were forgotten, and on sending my bill, some months later, I was politely informed by letter that "they were able to pay their bills," and that "it was entirely unnecessary for me to take an *inventory* of their household goods. My *professional services only* had been required." This was ten years ago, and the bill is still on my books. So it cost me just fifty-six dollars to look at that beautiful picture on the wall. It wasn't worth it. I can see better ones at the museum any day for a ten-cent car fare.

An elderly spinster once requested the loan of some good book on anatomy. Foolishly, I handed out Gray's, remarking that it was the best I possessed. She found some plates toward the end of the book which displeased her, and indignantly returned my book with the brief remark that "she did not care to be gratuitously insulted." Now, "Gray's Anatomy" contains nearly one thousand pages. She evidently saw *one* of them. She was a good-paying patient, but now another doctor gets her cash.

I meet an old lady, a stranger, at the church social, who kindly tells me of her ailments, her husband's faults, the trouble she has with her servants, and how many of her grandchildren have had measles and mumps, and when, and how long they lasted; also informs me that she has a bunion on her left foot and a soft corn on her right. Of course, I deeply sympathize with her, but offer no advice. I afterwards learn that "she likes me *personally*, but would not care to employ a doctor who takes so little interest in his patients."

A patient informs me that he changed doctors because his family physician now drives a pair of horses, instead of one horse, as formerly, "which is, of course, a very heavy expense, and *he must make the money out of his patients somehow.*" And still another tells me that Dr. Blank can't be *very sucoessful*, because he keeps no horse and carriage, and lives in a flat.

An exceedingly intelligent friend confidentially advises me to remove my bookcase with its well-filled shelves from my office, because doctors are supposed to know all about medicine without having to consult their books after they have graduated, and having so many books in sight has a bad effect on patients. And still another tells me that he was in Dr. Knumskull's office, and "there wasn't a book in sight, so *he can't know much.*"

There comes yet another who informs me that my rival across the street has the finest display of surgical instruments that he ever saw, in a glass case. So he must be a great surgeon and have a fine practice.

And a lady patient says: "Oh, doctor! Why don't you cover up those horrible instruments. They make me feel faint; they are so suggestive."

Another patient surprises me in the act of reading the morning paper, and says she always thought doctors were too busy to read the papers. And an hour later another patient asks me if I have heard of the terrible railway accident, six persons killed, etc., and on my replying that I had not heard of it, raises her eyebrows, also the corners of her nose, and says she thought all doctors would read the papers and take an interest in such things, "a professional interest, you know." And I am afterwards told by a mutual friend that the lady in question does not consider me a very *well-informed* man, for a doctor.

A smile! What a trifling act in itself, but how much it sometimes means. I once inadvertently surprised the husband of my patient in the act of kissing the nurse in the hall; and my involuntary smile cost me the good will of a rich young man, and on the flimsy plea of his wife's wish to try homeopathy for a while, I was discarded, and the lesson impressed upon me that blindness sometimes has its advantages, while deafness almost invariably has, and the complete control of the risible muscles is invaluable.

On one occasion, while impatiently waiting in the parlor for the patient's appearance, I gently kicked a pet spaniel which was gnawing my new trousers below the knee. The lady suddenly appeared on the scene, and poor Fido was caressed, while I, her faithful medical attendant during the preceding four long years, received no more telephone calls from that house. I afterward learned that a man who would ill-treat a dog was *cruel at heart.*

Love me, love my dog, was her motto. Kick my dog, and consider yourself dismissed.

The foregoing are only a few instances in which trifles played a conspicuous part in reducing my clientele. I might mention many more similar cases, but not to appear too pessimistic, I will mention a few more agreeable experiences, based on *trifles*, but which were instrumental in increasing my prestige.

For instance, I might mention the lady who took a liking to me from the very first, as it were, "at sight," because I chucked her little Johnnie under the chin on entering the room. The doctor must therefore be fond of children, was her conclusion.

Those little placebo tablets which were administered to little Katie who, on her return from the Sunday school picnic, had thrown up the very generous, indigestible luncheon usually provided on such occasions, and after having got rid of the trash and fallen asleep, really *needed nothing* (but whose fond parent thought otherwise), brought the tears of gratitude to the fond parent's eyes, and made her my friend ever after. She now boasts of my skill in treating children's ailments, and insists that Katie had a narrow escape from scarlet fever or some other dreadful disease.

Then, there was the gentleman who insisted on doubling my fee, because he claimed that I saved the life of his dear wife and child by the skillful use of the obstetric forceps, whereas it was just an ordinary case of uterine inertia, in which a good dose of quinine and an hour's delay would probably have served the purpose equally well.

The child who swallowed a penny, a good one, which, of course, would pass, with or without the placebo which was promptly administered, but for which skillful treatment I have ever since enjoyed the unbounded confidence of the family and their friends: "You saved our child's life, Doctor, and *you know* it, but you are *too modest* to acknowledge it; however, you have our gratitude all the same."

Bless their hearts; would that there were more like them; how happy we would all be.

There was that little trifle of a three-by-five-inch mustard plaster on the pit of the stomach to relieve vomiting, and which succeeded after the other doctor had administered five different kinds of medicine, with the only effect of increasing the disturbance.

And the family is glad to find at last a *doctor who knows something.*

The seemingly trifling act of putting a drop of oil of cloves into the cavity of an aching molar and covering with a drop of sandarach varnish, not only relieved the toothache instantly, but secured a good patient who, with her friends, has remunerated me a thousand-fold in the past few years.

Many similar cases might be mentioned in which the most trifling acts have turned the scale towards success or failure.

Trifles light as air sometimes exert a wonderful influence for weal or woe, and the above-mentioned cases are given merely for the purpose of calling attention to the importance of *little things*, which, though seemingly insignificant in themselves, may ultimately prove to have been the turning point from which the practitioner may date his advance, or vice versa.

Patients are, as a rule, very observant; more so, perhaps, than we are willing to admit, and while the doctor is, so to speak, "sizing up" the patient and his friends, he should not forget that they also are doing the same by him, and with the additional advantage of bringing more eyes to bear upon his actions, so that every little act is noticed by them. And a word, a look, a smile, or frown, which may be immediately forgotten by the doctor himself, is sometimes indelibly impressed upon the memory of the patient and his friends, and it not infrequently happens that afterwards, when the physician discovers that he has been supplanted by a rival, he will find on careful investigation that the change of doctors was due, not so much to lack of *skill* as to lack of *tact*. And that the idle word that he thoughtlessly allowed to escape him, has proved to be the dead fly in the ointment.

When we come to apply our theory of the importance of little things (trifles) to the scientific side of medicine, we find it too frequently overlooked or disregarded.

In the modern "so-called, up-to-date," practice of medicine, we are prone to consider everything only from an ultra-scientific standpoint, and while engaged in the industrious investigation of the infinitesimal, we are apt to lose sight of the trifles which exert so great an influence in the efforts of Nature toward the cure of disease. Having discovered, as we believe, the bacillus which has produced the pathological condition, we lend all our energies toward the destruction or extermination of the offender, forgetting that, in many cases, the recuperative power of Nature itself is amply able to combat the ravages of the germ, if only assisted in her efforts by the intelligent application of, in many cases, only apparently trifling measures. In this connection we might refer to the somewhat trite subject of fresh air and pure water, those two elements which, to the mind of the average layman, represent the most powerful enemies to health, to be constantly guarded against.

Even the doctor but recently out of college, must often have been impressed by the morbid fear exhibited by patients and their friends of those two most essential allies of Nature, in her efforts to effect a cure. Now, the giving of a glass of cold water to a fever-stricken patient is a trifling act, yet it often means the difference between a restless, disturbed sleep, and a peaceful slumber which conserves the patient's strength. The same might be said of fresh air, of which our patients are so often deprived.

Even in health we rise in the morning invigorated rather than depressed after sleeping in a well-ventilated room.

The simple, trifling act of opening the window a few inches, determines whether we shall inhale a life-giving elixir or a potent poison.

The trifling difference between a clean spoon or a doubtfully clean depressor or spatula taken from the pocket and used on the patient's tongue, has been known to turn the scale for or against the physician using it, in the estimation of the patient.

Even the neglecting to wash a thermometer before returning it to its case after using, is generally noticed by the patient or his friends.

On one occasion I refused (and justly, I think,) to allow a celebrated dentist to place his mirror in my mouth after notic-

ing that he had neglected to cleanse it since using it on another patient, and transferred my patronage to a dentist who scrupulously washed his hands before inspecting my teeth. Needless to say that the patients I recommended to the latter amply repaid him for his regard for trifles.

The difference between the trifling pain incidental to the opening of an abscess and *no pain at all* felt by the patient may seem too insignificant to the scientific surgeon, but it means a good deal to the patient whether a local anesthetic is used or not, especially if the patient be a child.

The liberal use of toilet paper (which can be immediately burned) for wiping away the discharge from the nose or mouth of a diphtheritic patient, instead of the filthy towels or cloths which are often used for that purpose, will sometimes limit to a great extent the risk of dissemination of the disease among other members of the family. The trifling cost of three or four feet of rubber tubing attached to a catheter, the distal end of which can be dropped into the receiving vessel under the bed, will prevent the unnecessary exposure which is sometimes so distasteful to a fastidious female patient. The careless passing out of a handful of tablets or pills from the doctor's pocket, as is sometimes done, must certainly create a less favorable impression on the patient than if such medicine is carefully placed in a neat box with directions written thereon. This is only a trifle, but worth while.

Even the little cotton swab on the end of a toothpick for the application of a remedy to the eye, and which can be afterwards thrown in the waste basket, is less costly, but preferable, to the camel's hair pencil, which may have done duty on many previous occasions, and with less risk to the patient.

Remember, there is a disease known as gonorrheal ophthalmia, also syphilitic iritis, which *might* be transmitted by that little camel's hair brush.

The extraction of a tooth is a trifling matter, provided you are an expert, and do not break it. Should that occur, however, you will wish that a dentist had the trifling fee, and you had retained your patient, for he will almost certainly leave you, and ever after give you a bad name.

The use of a clean bandage, or a slightly soiled one, will often determine whether you or the doctor across the street will receive the next office fee from that patient.

Even your prescription blank, bearing also a druggist's name, will often militate against you, especially if the said druggist's charges are high. The laity still cling to the absurd notion that doctors receive a commission from druggists.

There are many other trifles that might be mentioned, but which will readily suggest themselves to the thoughtful physician, and if the reader should impatiently cast this article aside, and condemn it on the plea that it deals only with *trifles*, I would beg to remind him that he had a fair warning in the *title*. And also respectfully refer him to our esteemed homeopathic brethren, who have always placed implicit faith in the importance and efficacy of *little things*.

"*Trifles make perfection, and perfection is no trifle.*"

Norwegian Names of Drugs Which Are Commonly Carried by Most Ships Flying Norway's, Sweden's and Denmark's Flags, Translated Into English and French—Ships' Disinfectants, and Their Value.

BY GEO. H. TICHENOR, JR., A. B. (TULANE), M. D. (TULANE),

Former Medical Inspector Louisiana State Board Health; Member Association of Officers and Surgeons Confederate States Army and Navy, Etc.
New Orleans, La.

The following drugs, according to the laws of Norway, must be carried in every ship's medicine chest. When a vessel is first fitted out in Norway, of course, all the names of its medicines in the chest are labeled in their language, but as the vessel sails from country to country, and runs out of different medicines, they are replenished at the last port from whence they sailed; consequently, the pharmacist

to whom they appeal for purchasing a new supply is often puzzled to decipher "jaw-breaking names," and the health officers and physicians who may be called on to attend the sick among the crew and passengers are often in a worse predicament.

The following list of drugs, with strengths and combinations, will be of great service to seaport health officers and attending physicians, judging from my own experience, especially as Norwegian ships are in the majority at every large port:

Norwegian—Natron (soda) dobbelt kulsurt. Bicarbonate soda, bicarb. natricus. French—Bicarbonate de soude.

Norwegian—Opiums draaber. Tincture opium; tinctura opii. (It is put up according to Ph. Brit, 1885.) French—Teinture thé baique.

Norwegian—Opium-bly-pulver. Opium, powdered. French — Thé baique en poudre.

Norwegian—Opium pulverat ana 0.03 ctgm. Acetate of lead, acetas plumbana, ½ gr. French—Acetate de plomb ana (0.03 ctgm.).

Norwegian—Opodeldok flydende (saebespiritus). Compound liniment of soap (liquid). Spirit saponis camphorat. French—Baume opedeldoct (liquide).

Norwegian — Piller afførende paa 25 ctgm. Compound pills of colocynth (of 4 grs.). Pilul. colocynth comp. French —Pilules de coloquinte composeés de 0.25 ctgm.

Norwegian—Karbol-jod. glycerin. Acid carbol, 1 gm.; carbolic acid, spirit dilut., 1 gm.; diluted spirit ana 16 grs.; tinct. iodi, 0.5 gm.; tinct. iodine, 8 grs.; glycerin, 10 gm.; glycerine, ⅓ oz. French—Acide phénique, 1 gm.; alcohol de 67° 1 gm.; teinture d'iode, 0.50 gm.; glycerine, 10 gm.

Norwegian—Kautsckuk spar a drap. Heft plaster.

Norwegian—Klorsurt kali. Chlorate of potassium, chloras kalicus. French—Chlorate de potasse.

Norwegian—Kviksølv-saebeplaster. Mercury plaster, soap plaster ana, empl. hydrarg., empl. saponat ana (Ph. Germ.). French—Emplâtre mercuriel, emplâtre de savon ana.

Norwegian—Lapis opløsning. Nitrate of silver, 10 grs.; distilled water, 1 oz.; sol. nitrat. argent (2%). French—Nitrate d'argent, ½ gm.; eau destillé, 25 gm.

Norwegian—Jodkalium i pulvere paa, 10 gm. Iodide of potassium in powders, ⅓ oz.; iodet kal. cont. French—Jodure de potassium en poudres de 10 gm.

Norwegian—Jodoform. Iodoform, iodoformium. French—Jodoforme.

Norwegian—Kamferdraaber. Spirit of ether with camphor (6—1). Æther, spirit camphor. French—Teinture étherée de camphre.

Norwegian—Karbolsyre, raa, tié. desenfektion. Carbolic acid, crude; acid carbol. crud. French—Acide phénique impure.

Norwegian—Karbolsyre, revset. Carbolic acid liquid purified; acid carbol. pur. liqvef. French—Acide phénique pure (90%).

Norwegian—Dover's pulvere paa 60 ctgm. Compound powders of ipecac of 10 grs.; pulv. ipecac opiat. French—Poudres d'epecacauan ha opia cées de 60 ctgm.

Norwegian—Engelsk salt. Epsom salts, sulphas magnesia. French—Sulfate de magnésie.

Norwegian—Heft plaster, alm. (unden terpentin). Adhesive plaster (without turpentine). Empl. adh. cummastice ext. French—Sparadrap adhesif.

Norwegian—Hoffmann's-draaber. Spirit of ether; æther spirit. French—Ether sulfurique alcoolisé.

Norwegian—Hostedraaber. Paregoric elixir; tinct. opii benz. French—Elixir parégorique.

Norwegian—Jerndraaber. Tincture of malate of iron; tinct. ferri. pom. French —Teinture de mars pommé.

Norwegian—Braekpulvere paa 1 gm. Ipecacuanha powders of 16 grs.; red. ipecacuanh. pulv. French — Poudres d'epécacuan ha de 1 gm.

Norwegian—Chinin-pulvere paa 1 gm. Hydrochlorate of quinine in powders of 16 grs.; chloret. chinic. French—Chlorhydrate de quinine en poudres de 1 gm.

Norwegian—Chinadraaber. Compound tincture of cinchona; tinct. chinæ comp. French—Teinture tonique de Whytt.

Norwegian—Citronsyre. Citric acid; acid citr. French—Acide citrique.

riorly, and with fingers and spud working up along the anterior and posterior wall of the cervix until we reach a point at about the junction of the cervix with the body, where we will enter the pelvic cavity; first, anteriorly, then introducing the fingers and grasping the body of the uterus, it is tipped forward and pulled down into the vaginal canal. The index finger is introduced beyond the broad ligament, and with scissors incisions are made just outside of the anastomotic artery, or between this artery and the body of the uterus, until we have severed the connection of the broad ligament to the uterus. We then operate likewise upon the opposite side.

Should it be necessary to remove the ovaries as well as the uterus, after introducing the fingers in the peritoneal cavity, through the opening in the vesico-uterine ligament, we bring down the ovary and ligate the pedicle produced by pulling down the ovary, removing one or both ovaries by this method.

We find by operating in this manner that only small branches of the anastomotic artery are severed and require only grasping with the hemostat. That is, it is not necessary to use ligatures to stop the bleeding, but merely grasping these small vessels with hemostats and twisting them will stop the bleeding; thus we eliminate the element of shock from hemorrhage, and the patient recovers speedily.

The only distress produced is that caused from the anesthesia. Most patients will recover and be able to leave the bed in ten days to two weeks and will be out of the hospital in three weeks. This is quite a contrast to those patients who are operated by the abdominal route, and quite an improvement over the method of operating and dividing the uterine or anastomotic artery,

In cases where this artery is severed there is always danger of secondary hemorrhage, while in the method described above there is no danger of such a complication.

1802 North Kingshighway.

The Early Diagnosis and Symptoms of Consumption — Arguments Drawn Therefrom for the Subcutaneous Injections of Oil.

BY THOS. BASSETT KEYES, M. D.,
Chicago, Ill.

The diagnosis of consumption should be based upon its symptoms, and not from tests as to the reaction of the system, for that is sometimes deceivable, while the symptoms plainly point out the course of treatment and ways of living which the patient should adopt. An old tubercular lesion may remain dormant and not cause the patient the least annoyance, or interfere with his health, providing he is living a proper life as to matters of food; indeed, by this means alone, through some change in the life of a tubercular person, as an occupation which has increased his appetite, or through change of diet, the disease has been cured.

While the tuberculin test has been usually advocated only in the early stage of the disease, where the symptoms are obscure, I do not remember it, for the reason that it very often produces in these cases more than a slight fever, and, in addition, may produce chills and general malaise and aggravation of the symptoms, which, lasting for some days, weakens the patient, takes away his scanty appetite, so that from the test he has often lost in weight and, as a consequence of all the conditions enumerated, has lessened, rather than strengthened, his chance of recovery.

That early diagnosis of consumption is so important has been the excuse of the stanchest advocates of the tuberculin test, but I take it that the pretubercular symptoms, which should cause alarm, are so prominent that they can not fail to be recognized, and were treatment began at this time it would be more as a preventive measure. But it is only too often that the consumptive patient does not seek aid in the early stage, or his physician, recognizing the disease, has spared him of the knowledge, sometimes the physician himself being at fault, if he has allowed the disease to advance. Though understanding human nature, we

know that some of these patients do not follow the advice in the manner in which they should; again, how many have made a proper study of this disease, and are able to plan a diet disguising the large amounts of butter and fats, so as to be relished by the patient, and which are so essential to the cure of this disease, together with other articles of diet which, by their mechanical action, aid in the digestion of these fats?

In the diagnosis of early tuberculosis we must first consider the following points as aids:

1. The appearance of phosphate in the urine.

Phosphatic absorption and fat assimilation are closely connected, so much so that when hogs are fed upon a milk diet, in which all fats are eliminated, so far as practicable, phosphaturia develops. The consumptive patient, passing large amounts of phosphates in his urine, is cured of these symptoms by the subcutaneous injections of oil, and it is evident that the assimilation of the oil produces conditions for the greater absorption and assimilation of the phosphatic salts.

2. Loss of appetite, some indigestion, and a dislike for fatty foods, anorexia, and nausea, with progressive loss of weight, inequality and dilatation of the pupil.

Such symptoms call for outdoor life and forced diet.

3. Sleep sweats, general relaxation of the system, and a tendency to sweat from slight exertion, with a rise of temperature in the afternoon, then morning expectoration and cough, perhaps pain in the affected lungs, or in the supraorbital region and neck, and sometimes hemorrhage.

These symptoms call for subcutaneous injections of oil, for by their use we strengthen the patient by building up nutrition, and we furnish material for maintaining the normal heat of the body. Nature, being thus supplied, does not seek to conserve and save her forces and fat tissues from too rapid oxidation, by cooling the body with perspiration at the expense of the vitality and force of the body. On the contrary, the substance for oxidation and care of diseased tissues is furnished by the oil injected, as well as the substance for furnishing force and vitality to the body.

4. The period of invasion of the germ is commonly marked by symptoms of a chronic bronchitis, without pulmonary signs.

The symptoms which we have enumerated are premonitory, after deposit of the germs; when these are being thrown off, with consequent symptoms, the diagnosis is easy, but in the treatment of this disease we should not wait for advanced symptoms before beginning the treatment. The symptoms of cough advance with the amount and extent of inflammation of the lung tissue, and the sensitiveness of the throat, and the amount of anemic, blood pressure, and cardiac disturbances. When all of these symptoms have arrived, coupled with loss of weight, it is not necessary to confirm our diagnosis by finding of the germ. The general physical appearance of our patient, together with the symptoms, enable us to base our diagnosis.

Without entering upon the differential signs of this disease, we may mention signs of the diseases which have been said to be often confounded with tuberculosis, and from which differential symptoms should be kept in mind.

Chronic bronchitis, chronic streptococcic, or influenzal pneumonia, and syphilis of the lung, are among the inflammatory diseases of the lung which bear closest resemblance to tuberculosis. But when symptoms of wasting disease of a chronic type are present, with or without severe pulmonary symptoms, they call for, as the principal part of their treatment, nutrition, and this is best given by subcutaneous injections of oil. The same as to treatment can be said of these other diseases which may be mentioned as having symptoms similar to those of early tuberculosis, such as pernicious anemia, leukemia and pseudo-leukemia, but which require differential diagnosis; not on account of treatment so much as for the satisfaction of the patient and physician. As the symptoms of tuberculosis advance, all of the premonitory symptoms increase in severity and give rise to certain signs, characteristic of pathological conditions, which varies according to the form of disease and the resistance of the body,

always kept open, fronted the sea, and was but a few steps from the beach. The first fly was caught after she had alighted from a soaring flight about the chamber. This fly was as alert, active and seemingly as healthy as any other, and not at all easy to catch. Situated upon both sides of the abdomen, near the hinging of the wings of the insect, were bright, red projections, standing out from the brown body surface like the wattles on a game-cock. The excrescences, to my sight, aided by a hand glass, appeared like small coral buds, and were immovably attached to the first abdominal segment. After a few moments' close observation, what might prove to be legs extending out from beneath one of the little bulb-like bodies, could be made out. Confining the fly in an open box of about a cubic foot and a

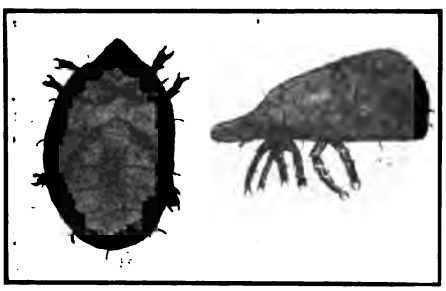

FIG. 1. Housefly Parasite Viewed from below. (Drawn from Life.)

FIG. 2. The Parasite from the Side. (Drawn from Life.)

half capacity, guarded by ordinary mosquito netting, I caught and imprisoned together with the affected insect some twenty-five other flies, of both sexes and of all sizes and varieties.

Believing that what had at first been taken for an oozed blood drop, probably drawn from my own body, and which in some unaccountably way had burst through a gorged fly's body, without much evident disturbance of bodily function upon the part of the insect, was some form of parasitic animal making a host of the fly, I desired to learn what chance there was for dissemination amongst its fellows.

Twelve hours afterwards, when I came to examine my captives, which had been amply supplied with food in the shape of milk-soaked cake crumbs, serving even to attract other insects from the outside as well, I found that all had escaped save one, and he was not the fly which had carried the parasites. As the mosquito

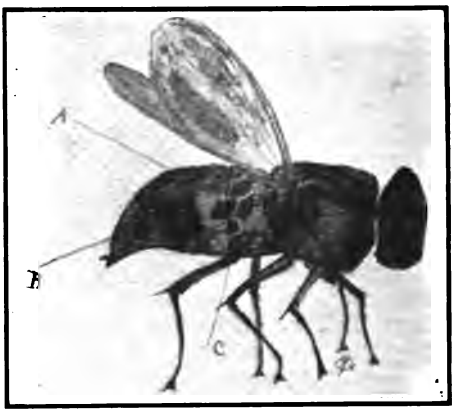

FIG. 3. Showing five of the parasites fastened to the abdominal segments of the insect; relative size of parasite and host well shown. (Drawn from Life by the Author.)

bar had been securely fastened, it was only possible for the flies to have escaped by boring and wriggling directly through the meshes, in a similar manner as that employed by a fish escaping through a net pocket.

The second specimen of parasitic-bearing fly was noted upon the day following, being observed soaring about in the room. It was not the same fly I had had in my possession, for the reason that this was a

FIG. 4. Section drawing of housefly suffering from parasitic disease (A, B) areas which have supported the parasites; in these localities the bristles have been clipped by the parasites. (Drawn from Life.)

much larger insect. While the first was observed to have had as many as eight of the little coral bodies upon its body, the second had but four clinging upon the

sides of the abdomen, and one far removed upon the last body segment.

Examination of the mosquito netting failed to disclose any of the parasites which might have been dragged off during the fly's passage through the netting, though such an event could be hardly possible, considering the protected sites beneath the wings, chosen by the parasites as points of attachment.

The second fly eluded all efforts at capture, and after giving me chance for but two or three observations, darted out of the window.

The third specimen was captured almost a week later upon a railing in one of the deserted ocean pavilions. This fly had two of the parasites upon its body. One fastened upon each side to the first segment of the abdomen, sheltered beneath the wings behind the hinge. This fly, a male, was distinctive by the rainbow brilliancy of its wings. It was, when captured, as busy in its reconnoitering flights as any other of its kind, and seemed undisturbed in being forced to play the role of host. But seven other flies were noted, after a careful observation, about this large pavilion, the white walls of which made the search for insects a comparatively easy one. To insure against the escape of the fly and its parasitic guests, all were sealed up in an air-tight receptacle until a leisurely-conducted microscopic examination might be made.

Description.—Systematic study of the parasite demonstrates an oval, or distinctly lemon-shaped body of a coral red color, being one thirty-second of an inch (0.8 mm.) in length, sparsely covered with short, prickly, red bristles. The surface of the body presents a roughened, granular appearance, not unlike the minute granulations seen upon a healing wound, and is, doubtless, due to the scale or plate formation entering into the makeup of the external body wall. Five distinct flexures, extending completely across the body, in an irregularly convex direction toward the head, and more pronounced upon the ventral surface, divides the insect into six segments. Aid to locomotion and additional security when fastened to the body of the host, seem to be their function.

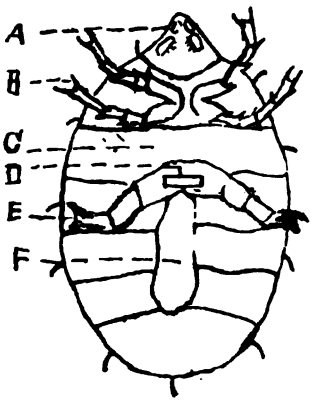

FIG. 5.

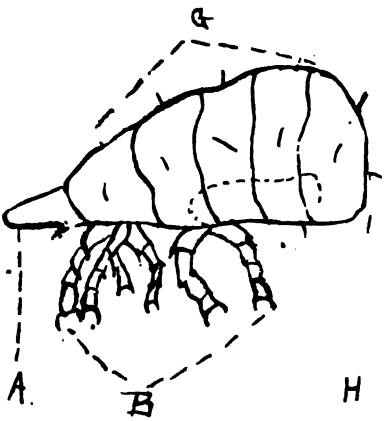

FIG. 6.

FIG. 5. Diagram of housefly parasite. (A) Headpiece and mandibles; (B) fore legs; (C) body; (D) tube connecting the two sides of the animal's digestive apparatus; (E) hind legs; (F) stomach.
FIG. 6. (A) Headpiece; (B) legs; (G) body segments; (H) surface bristles.

Locomotion is secured by means of three pairs of legs, two of the pairs being arranged together upon the second segment, and a third larger pair behind, fastened beneath the second and middle segments. The legs are jointed, covered with a number of fine, red hairs, and end in pincer-like projections. The hind legs are much longer and thicker than the fore, the clawlike extremities being flatter and stronger.

From the claw-like tips, and from the fact of the parasites having been constantly found upon the first abdominal segment, it seems probable that the little

animals are not given to roaming over the body of the host, to which they have attached themselves.

Extending for about one-third the body distance backward from the hind legs, is a dark blue, rounded, oblong, granular body.

Rupture of the outer wall of the parasite sets free a quantity of red coloring matter, after which the parasite becomes of a brownish-yellow hue, and the oblong body, capped by a tubular crossbar of blue, becomes more definable. The tube and receptacle, with the mouth and jaws in the headpiece, united by a minute channel, without doubt make up the major portion of the animal's digestive system. Action of the parasites upon the fly's body is manifested by an irregular area about the size of the parasite itself. The short, sharp bristles which cover the host's body

FIG. 7. Diagrams showing relative size of housefly parasite. A, housefly parasite; B, Ascarus scabiei (itch mite) giving rise to a disease of the skin called itch; C, pediculosis pubis (crab louse).

are found clipped smooth to the surface, as a sheep-cropped lawn, probably due to the action of the parasite in its endeavors to get close to the host. In addition, the affected areas are somewhat darker, roughed and granulated, seeming to imply that the parasite draws its nutrition from the host more by a gradual suction action through the cutaneous surface than by puncture and rapid withdrawal, as manifested by the ordinary mosquito bite.

The little animal, which might well be known as the coral parasite, for its presence when first observed recalled vividly to my memory the beautiful red coral to be seen in the depths of tropical seas.

Mr. Chittenden, acting chief of the Bureau of Entomology of the United States, Department of Agriculture, Washington, D. C., in a correspondence, has stated that the specimen described is probably a *trombidium muscarum*, of the family of harvest mites or "chiggers." Referred to Mr. Nathan Banks, the department specialist in comparative entomology, that gentleman stated that while the specimen sketch certainly pictured the young of the *trombidium*, he was not positive that it was *muscarum*.

The pathological significance of the genus *trombidium* rest in the larval state of the animal's existence. They are considered not true insects belonging to the order *Arcarina*, *exapoda* and members of the class *Arachnida* being associated with ticks and spiders.

These little animals are found pretty generally distributed over the world, being commonly but erroneously known in the Eastern States as "ticks," in the Southern and Gulf States as "chiggers," in Central and South America as "red bugs." In England and Scotland they are called "goose berry bugs." Upon the continent of Europe and in Japan the presence of the mites often cause great annoyance in rural districts.

The mites are found to inhabit damp localities, as along the edge of river banks, in the forests and "bush." When seen in such places they are found to occupy the under surfaces and shaded portions of leaves and shrubbery, as the majority of varieties avoid direct sunlight.

Mr. Banks, describing the life history of the harvest-mite, states that the female deposits its eggs in the spring of the year to the number of four hundred upon or in the ground. These later develop and attach themselves to some form of insect hosts. Maturing, they later drop off as full grown *trombidæ*.

The larved form have six legs, while the adult mite has eight. Parent mites are predaceous on true insects.

In his paper upon "Chiggers," published under the sanction of the Department of Agriculture, Mr. Chittenden has described the symptoms and mode of attack of these mites upon the human body. Burrowing into the skin, the animal becomes engorged with blood and sets up an inflammatory reaction over an area of from a quarter to three-quarters of an inch in extent. A feverish con-

dition of the skin comes on within an hour or so after the attack, or may be delayed for from twenty-four to forty-eight hours subsequently, varying with the susceptibility of the individual attacked to the poisonous effects of the animal. Children suffer more than do adults, and young women more than older women, doubtless due to a more delicate skin. After long residence in infected localities a form of immunity develops in the individual, due to (1) a toughening of the skin, and (2) to inoculation from infection.

The portions of the human body most affected by the results of these insects are the feet and ankles, about the knees, neck and armpits. Preventive treatment for those who have been exposed to mite-infected regions is a hot bath containing a strong solution of salt, or soap. After infection has commenced, sulphur in the form of the ointment or flowers of sulphur, dusted upon the body and in the clothing. Napthaline has been successfully used by Dr. L. O. Howard, in Mexico, and Mr. E. A. Schwartz, in Cuba, against these pests. Ammonia, bicarbonate of soda (cooking soda—salaratus), carbolic acid solution ten per cent, dilute tincture of iodine, collodion, may be applied. Alcohol, camphor, oil of peppermint, afford but a temporary relief.

49 East Sixty-Fourth Street.

[Written for the MEDICAL BRIEF.]

The Practice of Homeopathy.

BY N. SISCA, M. D.,
Killarney, Queensland, Australia.

(Continued from page 900, December, 1906.)

Single Remedy.—Much need not be said of this, the last of the three fundamental principles of homeopathy, and the meaning of which is that we should never give more than one medicine at a time, and that medicine should be the one, the "pathogenesy" of which covers, if not all, at least a large majority of the objective and subjective symptoms of the case, or what in homeopathic phraseology is known as the "simillimum."

From the homeopathic standpoint, this is as much a corollary of "similia similibus" as is the principle of the reduced dose, and, theoretically speaking, it would, no doubt, be most desirable and convenient to find one remedy quite sufficient to meet the requirements of each case, but in practice there are serious obstacles in the way.

First, it would, I think, be rather difficult to prove that in every case the so-called "totality of the symptoms" belongs to one remedy, and the homeopaths themselves tacitly admit that it is so when they prescribe medicines, as they almost invariably do, "in alternation."

Second, even if it were not so, it is not every practitioner who can boast of being able to hit upon the "simillimum" at a few minutes' notice. So that, on the whole, I think we may regard the principle of the single remedy more as an esthetic desideratum than as anything which can stand the test of everyday requirements. Homeopaths are wont to make fun of what they facetiously call "allopathic blunderbuses," and to pity us because, they say, we are not able to tell which of the many ingredients in our mixtures is the one that fails or succeeds in curing. But we, in our turn, while admitting at once that many of our prescriptions might with advantage be much simpler than they are, would ask them kindly to tell us, when they prescribe two or three medicines in alternation, whether it was number one, number two or number three that turned out to be the "simillimum." The fact is, that in most cases one remedy is not sufficient, and that, therefore, by persisting in giving only one remedy, we would simply waste time and thus run unnecessary risks.

In years gone by many a follower of Hahnemann honestly believed that it was not safe to have medicines bottled up and kept on the same shelf, as the very fact of their being so close together would spoil them. But we do not hear much of that now, and I could quote several instances in which homeopaths of good standing were recently broad-minded enough to admit that to prescribe two, or even more, medicines together is not, after all, the unpardonable sin which they have been in the habit of believing it was. And, further, were I inclined to retaliate, I might ask how many hundreds, if not

thousands, of homeopaths have not prescribed the famous homeopathic pot-pourris, known under the name of "Mattei's remedies."

For my own part, I know of no reason why medicines which are not incompatible should not be given together, especially when the case is a serious one and time is of great importance.

And this closes, so far at least, as we are concerned, what our friends, the homeopaths themselves, will probably admit to be a brief, but fairly accurate, summary of the history, theory and principles of homeopathy. They are quite welcome to find flaws and imperfections in it, but I feel confident that this time they will have no reason to complain of misstatements and misrepresentations. I have purposedly left unnoticed such things as "Dynamisation," concerning which the Hahnemannians themselves can not agree, and "Keynotes and Characteristics," which are seldom reliable, and which can only serve the purpose of boiling down homeopathy to a very undignified epitome of therapeutic practice, and, worse still, of further increasing the already too numerous army of homeopathic quacks.

The remaining notes will be devoted to a study of the practice of homeopathy, and to a brief outline of comparative *materia medica.*

[Written for the MEDICAL BRIEF.]

Oletheric Tincture of Biniodide of Thymol.

BY EPHRAIM CUTTER, M. D.,
West Falmouth, Mass.

To a certain extent animal oils have been in use in America because of their osmotic action through the skin. Skunk oil has been much employed for years. The oil of the common goose has also been used; as, for instance, when a babe had a dry cold in the nose. Goose oil placed at night on the nose skin disappeared by osmosis before morning with good effects. The oil of the common hen (*gallus domesticus*) has been used in New England for years in home medicine, and also by the late Dr. C. N. Allen, of Rutland, Vt., forty years ago, who never would have employed it were it not reliable. Skunk oil is expensive. Goose oil*, used by Hippocrates, it is said, is not easy to obtain, but hen oil is procurable in almost every habitable place of man. For this reason, after reading the able article by a German physician on the combination of thym. I_2, with an almost unknown oil by a difficult pharmacal process, I thought I would experiment with hen oil and the biniodide of thymol. Not satisfied with this, I added ether, so that my formula is as follows:

℞ Hen Oil.....½ ounce.
Biniodide of Thymol.....½ drachm.
Sulphuric Ether.....½ ounce.
M.

This, when left to stand, gives a clear liquid, easily applied externally.

When the ether has evaporated it leaves an oily solution of thym. I_2 that answers well where the parts are too dry, as in the ear (excellent). Or a bandage can be applied and then soaked in the oletheric (oleum-ether) tincture. But for most external purposes I prefer the ethereal tincture, as the thym. I_2 will dry on and hold where no bandage can well be put. But the internal use of the oletheric tincture is surely interesting. Today a gelatine vaginal capsule filled with the oletheric tincture was introduced into the rectum, previously anointing the anus with mutton suet. In less than four minutes the patient experienced the taste of biniodide of thymol. The severe neuralgic pain in the rectum was relieved. Surely hen oil was useful here in introducing the thym. I_2 into the circulation as an analgesic. This experience has been had more than once. It seems as if the penetrating power of this oil might be utilized in the use of other drugs. In my opinion, biniodide of thymol is one of the best in the *materia medica. Verbum sap.*

After being with the BRIEF for some time, I have decided that I do not want to practice medicine without it, as I consider the BRIEF the most practical common sense journal published. Inclosed you will find $1 postal order for the BRIEF for another year.—E. M. HUGHES, M. D., Wylie, Texas.

---

*Also suggested by Dr. Jackson, dermatologist of New York as a vehicle for iodine, etc., in skin diseases.

[Written for the MEDICAL BRIEF.]

"Deadly Parallels" in Disease.

BY JOSEPH D. HARRIGAN, M. D.,
New York City.

In a recent paper I spoke of the necessity of not long losing sight of the fact that the essentials of many of the epidemic diseases were the same, and that we were not justified in manufacturing new diseases on the slight differences arising from splitting hairs over mere accidentals.

Gradations between the mildest cases of a certain disease, as, for example, typhoid fever, and most severe and deadly forms of the same disease, are acknowledged to exist by the most eminent writers upon the subject. Likewise the gradations are admitted to be almost innumerable.

Thus, Liebermeister says of typhoid fever:

"The diseases which are produced by the specific poison of typhoid fever differ a good deal among themselves. Some of these diseases are so serious that life is inevitably destroyed by them; others are so trifling that patient and physician are left in doubt whether there were really any disease at all. And between these extremes we find every gradation, together with manifold modifications and combinations."—(Ziemsen's Cyclopædia, Vol. I, p. 76.)

Lebert says, in his work on cholera:

"We include under the term 'Asiatic cholera' the diarrheas which occur during the prevalence of an epidemic, cholerine, and the well-defined grave forms of the disease. That all three are expressions of the disease itself, and not simply different degrees of it, is proven by the facts that the simple diarrhea often terminates of itself without leading to cholera; that the grave forms of cholera not unfrequently begin precipitately without previous diarrhea; and, finally, that cholerine occurs mostly without previous diarrhea, frequently does not turn into cholera, and may present in the most positive manner all the signs of the graver forms—only a few of these signs, of course, being present in one and the same case."

Again, Liebermeister, speaking of typhus fever, says:

"It is now agreed by almost every one that among all the affections which have been called typhus, we can distinguish three different diseases, each of which is produced by a specific poison. These are exanthematous typhus (typhus fever), abdominal typhus (typhoid fever) and relapsing fever. * * * Although at the present day this idea of a specific difference between these three forms of typhus is generally recognized, there is, at the same time, a general belief that they are very similar to each other. They are looked on as members of the same genus or of the same family. In the same way as we see in the exanthemata a natural group of different diseases which resemble each other in their symptoms, course, and mode of infection, so the typhoid diseases may be looked on as a group which includes typhus fever, typhoid fever, and relapsing fever, even the plague and yellow fever."

But why stop at these latter?

Why not continue through cholera, the black death of the Middle Ages, and a few more of these terrible complaints? And why not commence further up the line, say, at influenza, for a unit as a starting point for these gradations? We are aware that for ages influenza has been looked upon as the great pioneer in epidemic diseases. Its sojourn with us is measured by years. It has scarcely disappeared from the earth when it returns to the attack with the same and even greater vigor.

Its virulence and malignancy can well be compared with those of any of the other diseases.

To any one with a wide experience with this disease, the most important fact that strikes him is the universal involvement of the mucous membranes.

That is, the effects of the absorption of the disease-poison are shown mostly on the membranes. Many cases there are, however, where the structures of the various organs are also affected, indicating thereby a more intense degree of potency of the poison or else a greater amount of it absorbed.

In the course of many years of experience in dispensary work, I have

treated perhaps fifty thousand cases of influenza, and have watched with interest the varying phases of the disease, from the mildest forms in which a coryza with congested fauces and a mild conjunctivitis accompanied by cephalalgia, announced the presence of the disease, all the way down through the various gradations that showed involvement of the entire digestive system, as likewise the various organs of excretion.

Cases in which the gravest symptoms showed themselves have been so numerous as to attract special attention, and it has been with the most profound interest that I have watched the gastric, the renal, the enteric, the hepatic, the pneumonic, the cephalgic developments, with their resulting effects as shown by the icterus, the biliousness, the almost choleraic discharges, with disturbances of the cerebro-spinal system, running all the way from ordinary nervousness to severe inflammations.

Judging by the symptoms exhibited in various cases, at times I have almost felt justified in calling them, respectively, cholera-influenza, typhoid-influenza, yellow-fever-influenza, etc.

This may sound ridiculous to some accustomed to drawing rigid and inflexible boundary lines around each group of symptoms, and bestowing names suggestive of the conditions present in each group.

But if we would take a bird's-eye view, as it were, of the whole panorama of epidemic diseases, and forget for the moment the nomenclature, or at least subordinate it to the underlying conditions and not to permit it to dominate them and us, swerving our judgment, ridicule, I think, would vanish. If there are gradations between the lightest and most severe forms of a certain disease, *i. e.*, of one certain group of symptoms, is it not also possible to find gradations from one disease into another? More especially as it is acknowledged that the symptoms in certain cases are almost impossible of differentiation.

The mere presence or absence of certain symptoms does not always prove one disease to be entirely different from another. There may also be a transposition of symptoms, the usual sequence not being always followed.

To illustrate, take for example an attack of influenza in which the absorption of the disease-poison is so rapid and abundant that the patient is prostrated dangerously from the very commencement. The sequence of symptoms does not eventuate as in an ordinary attack. The disease may be ushered in by a profuse diarrhea and intense biliousness.

The writer can truthfully assert that he has had hundreds of cases in which the symptoms complained of by the patient were entirely referable to the stomach and intestinal apparatus. The symptoms of "cold," etc., were entirely subordinate to the graver symptoms affecting the entire digestive system, as likewise the excretory functions.

Surround these cases with the climatic influences of a southern atmosphere, soil and flora, and who can say what the developments would be?

Does any one doubt but that the symptoms would be intensely aggravated, their sequence possibly disturbed, and that also entirely irrespective of "germs" as a factor in the matter?

If one were to compare the various epidemic diseases together, not for the sake of discriminating one from another so much as to identify the symptoms common to them all, with a view to harking back to what might be found as a common cause of these symptoms, I think the result would be surprising.

Take, for instance, the matter of cholera. It commences usually, as we all know, with a profuse diarrhea. Then comes the stage of reaction. In this stage, to quote Lebert:

"Congestions frequently occur in the head. The face, under these circumstances, is reddened, but unequally, so that it has a spotted appearance. The eyes are congested and lachrymose. Most patients complain of a fullness and heaviness in the head, or of a dull headache, either general in character or seated in the forehead or occiput. Roaring in the ears is frequent. Notwithstanding a certain tendency to somnolence, the most enfeebled patients are usually sleepless. * * * In a still later stage the so-called cholera eruption

shows itself. This eruption is at one time of erythematous, at another of urticarial character, or it may show a roseola-like appearance."

Verily, one is tempted to exclaim, "Influenza reversed!"

Except for the purely catarrhal symptoms, which are distinctive of influenza, both sets of symptoms are of such striking similarity, only differing in their sequence of arrangement, that they call for more than mere superficial attention and investigation. Concerning the digestive symptoms in influenza, Zuelzer says:

"The mucous membrane of the digestive organs is likewise affected in many cases, although generally not to so high a degree. Loss of appetite, increased thirst, a coated tongue, a bad, pasty taste, sensitiveness of the epigastrium, and, not infrequently, colicky pains and diarrhea, or nausea and vomiting, accompany the disease."

As to the purely catarrhal symptoms, one might almost say, had the diarrhea commenced first, the catarrhal symptoms would hardly have had a chance to develop.

But then, according to some, it would have been another disease, and if severe enough, we might even have called it cholera!

Certainly there is a sufficiency of identity so far in the symptoms as to make it extremely interesting, at least.

Turning to the nervous system, Zuelzer says:

"The prostration of the strength is very great from the beginning; the patients feel extremely weak and exhausted and soon take to the bed. * * * We regularly find, together with considerable depression, very severe pains in the limbs. * * * Patients complain particularly often of hard dragging or boring pains in the calves, the hollow of the knee, the shin bone or the back. * * * In the most severe forms were sometimes observed painful cramps in the calves."

As regards the expression of the countenance, the same author states:

"The patients have a suffering, anxious, and depressed look. According to Landouzy and Biermer, they sometimes have even a typhoid appearance."

Compare the digestive and nervous disturbances of influenza now with those of cholera. According to Lebert:

"Disturbances of the digestive organs are almost constant; there is a bad taste, a thick and heavily coated, yellowish tongue, which is sometimes fissured and dried. There is loss of appetite, thirst, nausea, occasionally vomiting, constipation or diarrhea, or both alternately, distressing meteorism, and illio-cecal pain, especially on pressure; cramps in the extremities sometimes occur."

The typhoid symptoms of both diseases are almost identical.

"The so-called cholera-typhoid is one of the most common forms of protracted convalescence."

Quoting from both authors hitherto mentioned, Zuelzer and Lebert, I submit a few more symptoms common to both diseases that seemingly require only equality of intensity to be identically the same.

Thus, for instance, in cholera:

"Among the complications of the convalescence or of the typhoid state * * * are diphtheritis of the larynx, or pharynx, intense bronchitis, pneumonia, pleuritis, dysentery, diphtheritic inflammations of the bladder and female genital organs, and parotitis."

Comparing these with influenza, we find:

"Among them (the sequelæ) are to be counted such cases as present an intense catarrh of the conjunctiva or of the ear, as a concomitant local affection, or of tonsillitis, laryngitis, bronchitis, or of pharyngitis of considerable severity. Frequently there are only hyperemia of the lungs and intense bronchitis, but also frequently catarrhal pneumonias. Pleurisy, *without* accompanying inflammation of the lungs, appears to be rare. *Croup* and false croup are sometimes present. *Parotitis* with salivation is sometimes observed.

The statements of the earlier observers about the complications of influenza with exanthemata, such as miliaria, roseola, urticaria, petechiæ, scarlatinal spots, erysipelas, etc., seem to refer, as Biermer assumes, chiefly to miliaria and urticaria."

I make mention of these eruptions here to show that such eruptions have

occurred, exactly in an analogous manner to the similar eruptions in cholera.

They are intimately bound up with certain forms of the disease, just as the erythematous rash due to eating shellfish with some people, is connected with the irritation to the stomach caused by this kind of food; or just as the rash of typhus fever is part of that complaint.

Thus, we see a wonderful similarity between the various symptoms in these two diseases.

As far as calling the local affections "complications," we are no more justified in doing so than in referring to the laryngitis, the meningitis, the osteitis, etc., etc., of tuberculosis as complications of that disease.

They are all part and parcel of the complaints, and are given in comparison in this article in an humble endeavor to show that there is a foundation or groundwork upon which the superstructure of epidemic diseases is built.

This foundation seems to be the world-wide affliction known as influenza.

Taking this disease as the unit or starting point and making due allowances for the changes, it must undergo in its course over the world, encountering, as it does, marked differences in chemical constitution of air, soil, water, and exhalations of the varying flora of the different countries, we ought certainly come to a much better understanding of the superstructure and what is most important of all, a far better insight into the pathalogical conditions upon which the symptomatology of these diseases is based. Without such point of departure we are like a mariner without a compass.

Always standing out prominently throughout the ages as the most universal of the epidemic afflictions around which the others seemed to circle and hover, and follow in its train, influenza should serve as a basis of calculation just as the North Star does among the constellations.

It is the key to all the other epidemic diseases. Thoroughly mastered in all its details it furnishes the cipher by means of which the mysteries of the other great universal afflictions may be read.

Through them all runs the influenzic strain. Modified by various circumstances and conditions arising from mostly local causes, still throughout them all we can readily perceive a striking similarity, a family resemblance, as it were, that points unerringly to influenza as their great progenitor.

Limited by space I have touched lightly upon the analagous symptoms of but two of the epidemic diseases. A comparison between several will, I have no doubt, prove of the highest interest.

668 Lexington Avenue.

Suggestion as an Adjunct to Regular Therapeutics.

BY W. T. MARRS, M. D.,
Peoria Heights, Ill.

Suggestive therapeutics, or psychotherapy, has a proper and legitimate place in medicine, but should be controlled alone by medical men. It is not a thing separate and apart from regular practice. It goes with the every-day work of the physician, whether he be regular, eclectic or homeopathic. Of late years quacks and irregulars have almost taken suggestion as a remedial agent out of the hands of the profession, thereby causing this branch of medicine to, in some measure, fall into disrepute. This is not as it should be. Many ailments and perversions can be reached through the influence of the mind, as they can be in no other way.

The physician is the only person to make application of this agency with any degree of accuracy, for he alone is competent to diagnose properly. Indeed, it is simply the business of the physician to put an ailing person in that environment which will best enable him to recover. It is his business to look into the patient's mental and psychic atmosphere as well as the kind he breathes.

Viewing the matter comprehensively, the doctor practices suggestion every day of his professional life. This he does whether he wills to do so or not. One of the chief differences existing among medical men is their personal equation and the manner in which they impress patients. The doctor who most readily

grasps the patient's psychic wants and needs will, other things being equal, stand the best chance of curing the patient. Such a man is a metaphysician who sees and takes cognizance of many little points which others would pass unheedingly by. He sees in his patient the half-shed tear, the suppressed sigh, the pent-up emotions and defeated hopes and aims. A little timely and kindly talk from the medical man may accomplish better results than a prescription sent to the corner drug store. Think of the lonesome patients in hospitals who toss about restlessly and bide the time for the doctor's arrival each day. They are cheered and animated by the pleasant greeting and encouraging words of the doctor if he be a man who radiates sunshine. But if he happens to be of pessimistic turn, woe unto his patients.

Suggestion should be given timely and judiciously, when it adds materially to the efficacy of medicine. Suggestion may be given by words, acts, gestures, insinuations and a thousand different ways. The patient should always be measured, and our methods and manners gauged accordingly. Too much talk is calculated to defeat one's purpose. We all admire the person who talks enough but are inclined not to place our confidence in the one who talks too much.

When medicine is given for a certain purpose the attention of the patient should be called to the fact that he may experience specified results. It is a law of psychic phenomena that the things we ardently expect or hope for, are the ones most likely to be realized. This fact accounts for much illness in which periodicity is a factor. How many persons we hear remark: "About this time every year I have a spell of some sort." Many ailments as well as their alleviation depend upon purely mental influences. One patient of the writer cured himself of the tobacco habit, erroneously inferring that the medicine given him was for that purpose. One lady said she felt the cooling effect in her kidneys *immediately* after she had taken a dose of a diuretic mixture. Great is imagination! And by the way, suggestive therapy is simply the wild imagination of the patient directed in a way that is conducive to his best interests.

As already intimated, you can expect your best results from psycho-therapy when used to supplement medicine. It often takes a pill to drive down a suggestion. The patient usually desires something tangible to which he can anchor his faith. We give medicine to help a woman in labor. We tell her it will strengthen her pains, but not increase her suffering. The expectant attitude of the mind materially aids in securing the results desired. If we tell a tobacco or alcoholic habitue that the medicine—apomorphine or emetine—will cause him to fall out with those things, he will attribute his nausea to the specific (?) action of the remedy, thereby adding force to the treatment. If he be given strychnine or other tonic to build him up, the "building up" concept should be emphasized.

We sometimes hear reports of bread pills producing catharsis under certain conditions. This is on the whole an exaggeration. It is true that suggestion given under profound hypnosis may accomplish nearly anything. The post-hypnotic suggestion in its exact fulfillment is marvelous. But after considerable research, extending over a number of years, I do not think it a good practice to put patients into a state of deep hypnosis. However, there are stubborn infirmities that can be reached in no better way than by suggestion given under deep passivity.

Enuresis is a condition that is very amenable to suggestive treatment, for it is usually due to habit pure and simple. Belladonna, atropine, etc., may be given for it, but unless the treatment in some way arouses an auto-suggestion in the mind of the sufferer, no good results may be obtained. In addition to correcting hygiene the child must be given encouragement. His mind must be impressed with the idea that he is going to get rid of the nasty habit. A homeopathic physician was very successful in treating this condition. A regular man was not so successful, so he made inquiries, and found that his homeopathic brother gave *sepia*, sixth potency, one pill every thirty minutes. So the regular physician got a

batch of the little sepia pills and gave them half-hourly with results highly satisfactory. Later on he got to giving placebos, and found he was just as successful. The secret of the matter was that he gave *something* at frequent intervals. The child had the *cure idea* constantly before him which, in time, produced its effect upon nerve cells and centers.

The above incident naturally makes us wonder whether many of the thousands of drugs in daily use do not owe a goodly portion of their efficacy to suggestive influences. If a remedy appeals strongly to a patient's imagination, and he associates it with his particular ailment, he is likely to experience good results, whether the drug exerts any physiological action or not. The homeopathic physician is successful with his little pills which contain a millionth part of a physiological dose. Why? He searches out symptoms and makes the leading ones the storm-center against which the little pills are directed. The patient associates these symptoms with an alleged specific, and the effect upon the mind is salutary, to say the least.

The suggestions given with regard to the ailments named apply with equal force in hundreds of other cases. Suggestive therapeutics should, therefore, be regarded as an adjunct to other methods and measures. It has not been my intention in this article to speak deprecatingly of drug treatment. We have a few—very few—remedies that are nearly specifics, and many others that are useful. But, perhaps, physician and patient would be as well off if ninety per cent of the drugs in general use were relegated to the bottom of the sea. Medicine-taking, in the way that it is practiced, is a relic of barbarism. Suggestive methods —by some other name, perhaps—will, in the future, be employed in the treatment of all perversions and psychoses.

THE MEDICAL BRIEF is a fearless exponent of professional right and liberty. All that honest physicians desire is justice and individual constitutional protection. —W. H. SMITH, M. D., Shell Rock, Iowa.

[Written for the MEDICAL BRIEF.]

What I Have Observed in Twenty-Three Years Practice of Medicine.

BY E. E. TRUITT, M. D.,
Maquon, Illinois.

I have observed that some physicians, the older they get in practice, the less faith they have in medicine. I am not one of these, as I am thoroughly satisfied with the results that I have gotten from the administration of drugs, and am more gratified than ever in the success I have in removing disease. Persons will, and must die. This is no reason we should be discouraged with our practice, as we should know when a case is curable and when not. When you hear a physician remarking that the practice of medicine is a humbug, you can put it down that he is a failure *in toto*. That he is not a doctor by nature; he lacks talent, and is not educated in medicine. The natural doctor can see, by his excellent human nature, the unbalanced physiological processes, and if well versed in materia medica and therapeutics, can select remedies to restore them to normal, if nature is not beyond assisting.

We have observed that the longer he is in practice the more he works for the fee, than fame or the love of his profession. That about one-half of the people think that gray hair and a wise look makes him their choice, while the other half cry out old fogy, and think that he should retire. We think, as a rule, that the latter is correct. That the longer he is in the profession the less remedies he uses, and smaller doses; that the loss of a number of cases takes the conceit out of him, and he begins to learn that he can not save them all. That a certain number of patients will take advantage of friendship and think it will be all right with "Doc" if they do not pay him. Doc hardly thinks so, and soon will begin to naturally hate the calls of such friends. That it is best to be independent, even if you are poor. That it is best to not promise a cure in any case, as so much depends on the patient, and that we are treating a wonderfully and fearfully made body, and many phases may arise worse than the first.

That it is best not to explain too much of a patient's disease to them, but briefly and concisely. Not to make them feel that they are worse than they really are —simply for a fee. That in chronic cases to have so much per week or month for treating a case that the patient may realize that he is constantly in your care, and will be obliged to call and see you and have medicines renewed at times.

That you have a uniform system of charging—enough, but not too much—the same for all classes of patients. That to be honest and courteous to all—especially children. When we have a system of charges that are reasonable, and we have tried to be honest and conscientious in our relations to our patients, and they yet express dissatisfaction, we feel that we have done them no injustice, and have no remorse of conscience.

We have observed that the practice of medicine in most communities is overdone, and that only a few doctors ever get well off financially through practice alone.

[Written for the MEDICAL BRIEF.]

The Bible Myth of Eden, Adam and Eve.

BY GEO. F. G. MORGAN, BACH. DIVIN., M. D.,
San Francisco, Cal.

In the September number is a short article by Dr. Frank Bruner on the "Garden of Eden, Adam, Eve," etc.

It now seems surprising to me, both a theologue and a practical medico, that men of exact scientific training, as the surgeon and physician of today must necessarily be, can be so deluded by their earlier education and mythologic "religious" (?) instructions as to give ear and credence to such Oriental archaisms and snake stories as that mentioned in the Book of Genesis—above referred to.

The serious side of the matter is that, while modern theologues unwillingly admit that THE WHOLE "EDEN" STORY IS ONLY A FABLE, as all sensible people must see this talking-snake story to be; yet these same "theologians" go straight ahead with their doctrinal preachments built upon this very (pro-)genetic fable, and declare to their hearers: "Thus saith the Lord," as though they were really preaching the facts and truths of the universe, instead of imaginary things, founded on the above fable of the snake, the garden, the woman and her garden companion.

Who was the ancient "Adam?"

A man, male?

No! She was ancient Egypt's Goddess of Death, "Atum or Atoum."

Who was "Khaiva or Eve?"

She was the "Living-One, Kayed-out One," the female, the type of all living motherhood.

Among the ancients, names expressed some peculiarity of shape, form, color or use, etc. The human female was named from her principal organ and maternal function: "The Khun or Kun, or Ghun, Gun; Khuni, Cunie, Ghuni, Guni, Goni; the Meeteer, Mątre, Womb-Man."

The German's name for mother, "Mutter," and the English name "Mot-Her," both came directly from the Egyptio-Hebrew "Mut-Khora," the great "goddess of chaos," the reputed celestial first cause of the whole inanimate and animate universe.

In the Bible we find evidences of her worship by the Jews, in the "Golden Mice" that were carried with the "ark" and placed in the temple, to soften this goddess' anger against the people.

As "Maut, Mut, Latona," her visible representative was the shrew-mouse or fieldmouse. She was one of the Jewish representatives of the one universal Deity—motherhood.

The goddesses of Assyria, Babylon and Egypt always went in pairs. Thus, "Is" and "Net Pe Is," or "Is Is and Netpes." The goddesses "Tuni and Atoum or Atum." The goddesses of the "East," or of new life and birth and increasing power; and the goddess of the "West" or transition from the organic to the inorganic form. Thus the "East or Front" symbolized the New Birth, Infancy, Increase. The "West" or "Back," symbolized the Decrease, waning of power, Death.

To set forth the idea of ever-present existence, the Egyptians used the first and third persons of the verb To Be, I Am, Is; and the better to visibly describe the unbegun-unending nature of their deity, they named the Goddess-Mother the "Is-Is."

The Greek colonists from ancient Egypt took the name of the Egyptian sun deity, "Athen," and added to it the character "A," and thus formed their deity, "AthenA." They copied their parents, in adding the latter "A" to their deity's name, thus to symbolize that "A-thien-A" was "without beginning or end," just as the Egyptians had symbolized in "Is-Is," the Mother deity of all Egypt.

The Hebrew word "Eden" signifies "pleasure." The word now read in the Hebrew as "Gan, Gani," is given in the English as "Garden." Originally, the marks in under the Hebrew characters signified o, u; and the word read as "Gon, Gun; Goni, Guni—the Womb-Man." From it we get "gynecology, gonorrhea," etc.

The Womb-Man was the Bible's "Pleasure Garden," man's "pleasure garden."

Now the Bible fable tells us that the ancient snake sat up and talked to the pleasure-garden woman and urged her to the exercise of her womanly functions and maternal duties.

But, why thus on the part of this snake?

The "Re Ligio" of the Orient was and still is, the "Re Ligio" of the Family. It was, it is, the only known mode of Salvation from the Death of family extinction. Therefore, the mythic Rachel (in Genesis, chap. 30, verse 1) cries to the equally mythic Jakob: "Give me children, or else I die." And in Timothy, chap. 2, verse 15, we read of the woman: "Notwithstanding, she shall be *saved in child-bearing.*"

Now, among the acients the snake was the "Genius Loci," and it was made his special duty to preside at the parental function and the birth of children.

One of the commonest of ancient pictures represents the ancient snake deity sitting on his tail and presiding at the birth of the young god, "Erickthonius."

This picture and story were the originals of the snake story of Genesis, chapter 3.

The Bible deities were not "gods."

The "Us" deities ("Olohim") of Genesis, chap. 3, vs. 22: ("behold the Atoum has became as one of us") were *goddesses.* They were the current deities of their own and of their past days. The so-called "Iudhs or Jews," were Assyrians, Armenians, Babylonians, Persians, Greeks, Arabs, etc. They were *a sect* of Nature worshipers, ancestor-worshipers, like all the remainder of the peoples of their times. They were not, they never had been, a people. *They were a sect only.* Hence their deity was the One Mother Deity of that age of these nations.

This deity's name might differ in different localities, but Sacred Motherhood was and is one, is universal, in time and place!

Now, what does the snake god say to the pleasure-garden woman?

In Genesis 3, verse 5, he says: "The olohim-gods know that in the day that ye *eat* thereof, then your eyes shall be opened and ye shall become as the gods."

But what "eyes" were those that were to be "opened" by this "eating of the fruit of the tree of lives?"

Among the ancient Greeks and Egyptians, "Ops, the eye," was the goddess of maternity, and the representative of the maternal organ and of the maternal functions.

Now we can see what "eyes" were to be opened for Atoum and her companion-khaiva ("Adam and Eve"), when they should "eat of the fruit of the tree of lives in the middle of the garden."

Well, they ate and their "eyes were opened," and this is the mythic "curse" that was put upon the woman because she ate "of the fruit of the tree of lives," chap. 3, verse 16.

"Unto the woman he (she) said: 'I will greatly multiply thy sorrow and thy conception; *in sorrow thou shalt bring forth children.*' "

Why this "curse?" Because the woman had *eaten* of their man's "*tree of lives.*" They had had their maternal "eyes opened" ("Ops"), etc., etc.

A baby? Of course! This was the only result to be expected from this marital feast in the "garden."

The Greeks celebrated a marriage by the man and woman eating of the "Love apple, Quince."

The Romans celebrated the marriage by "Con-farretio" or "Taking the cake." The pontifex, the man and the woman each and all took a piece of a small, round cake held by the priest Each and all ate of it, and the ceremony was completed by

the intermarital, physical act. To be "well wedded" the couple must be "well bedded." The "eating" was a symbolic expression of and for the intermarital act. In the Bible this is clearly set forth in the Book of Proverbs, chap. 30, verse 20, thus: "Such is the way of the *adulterous woman;* she *eateth* and *wipeth her mouth and saith, I have done no wickedness.*"

Who thus "*ate*" and "*wiped her mouth?*"

The "*Adulterous* woman."

We thus see that this Bible "*eating*" was a figurative expression for the intermarital, the intersexual act.

Now the snake-deity had promised the two women of Genesis 3d that they should become as the Olohim-Goddesses—"gods" of the English Bible. In verse 22 the "Jehovah of the Olohim" says: "Behold the Atoum has become as one of us."

Not until she became a mother was the Oriental woman held in repute. It is so today in Turkey. The Turkish *mother* enjoys legal rights and privileges unknown to the sterile, childless woman.

The Hindoos teach this very same Bible doctrine, that in the act and fact of the intermarital function and service the parties thereto "become gods of the holy circle."

"In the day that ye eat thereof, then ye shall become as the (Olohim) gods," says the snake (see verse No. 5).

"Behold, the Atoum has become as one of us," say the two goddesses of Genesis, chapters one and three (3d to 22 verses.)

Thus we see a perfect concurrence in the Family Service—worship of motherhood—as set forth in the Oriental writings of the Hindoos and those of ancient Assyrio-Egypt, now known as "the Bible."

The ancient "Re Ligo" or "Re Ligio" was the consecration and sanctification of the human intersexual relation. It was deemed the supreme act of human duty. Unlike the merely transient and brutal relation of concubinage, the "Re-Ligio *bound again,*" and continuously, this sacred pair in a lifelong family bond, the man to the woman; and hence he became the "Us-bound, Os-bound;" bound to the "Us, Os—womb."

The Womb-Man is the Savior ("Is-Os") of the human race!

3440 Twenty-Second Street.

[Written for the MEDICAL BRIEF.]

Yellow Fever.

BY REGINALD B. LEACH, M. D.,
St. Paul, Minn.

After consulting all newspapers and journals of the time, and my mail, since July, 1905, I have the honor to submit the enclosure for the perusal and consideration of your readers who were afforded the splendid opportunity, in your issue of last year, of studying the epidemic situation as it was in New Orleans (particularly) in 1905.

As you will see by the enclosed letter from Dr. Sisca, of Australia, I had the honor to congratulate him on his comprehension of similia as delineated in your July and August numbers of 1906. As the Doctor is a great admirer of yours, I have the honor to enclose his recent favor.

Trusting that the enclosed report may prove of use to you, and that THE MEDICAL BRIEF may continue in its liberal spirit and gather thereby a large family of the more progressive medics, I have the honor to remain your friend.

Dear Dr. Leach—

It is with real pleasure that I ask you to accept my best thanks for your very kind and otherwise highly interesting letter. I heartily join you in wishing that many of my allopathic confreres may have their eyes opened, to part, at least, of all the good there is in homeopathy; and if the notes which are being published in the BRIEF will be of some help in that direction, I shall be more than satisfied. All the credit, however, will be due to the Editor of the BRIEF, and I sincerely hope that his moral courage will eventually be appreciated and rewarded.

I also have to thank you for the clippings enclosed in your letter and the printed matter under separate cover. I find in the *Monthly Hom. Review*, London, April, '98, a report of your memorial to the Senate *re* arsenization as a preventive of cholera, but your clippings are the first intimation to me of your agitation in New Orleans about yellow fever. The reception you met with at the hand of the medical society was to be expected, but you did your duty nobly, and the praise of all lovers of fair play for your

manly conduct all through the affair is yours by right.

Good-bye for the present. With my best wishes for your welfare, I remain,

Fraternally yours,

N. SISCA, M. D.,

North Sydney, Australia.

Sept. 14, 1906.

RESULTS FROM THE EXHIBITION OF ARSENIZATION AS A PROPHYLACTIC OF YELLOW FEVER AT NEW ORLEANS, LA., AUGUST, SEPTEMBER, OCTOBER, 1905.

Population of New Orleans in 1905 (U. S. Census)	327,000
Immunes in New Orleans in 1905 (N. O. Board of Health), about..	16,000
Residents absent during epidemic (N. O. railway officials), about..	11,000
Arsenized persons in New Orleans, 1905 (N. O. *Lumber Journal*)	200,000
Non-protected non-immunes in New Orleans, 1905	100,000
Total Yellow Fever cases in New Orleans (1905 Government daily report)	3,396
Cases among non-protected, non-immunes (Government daily report)	3,391
Cases among two hundred thousand arsenized (Government daily report)	5
Deaths among cases in non-arsenized (Government daily report).	448
Deaths among cases in arsenized (Government daily report).	None

The Mad Stone.

BY H. D. FAIR, M. D.,

Muncie, Ind.

The physician is often asked to give an opinion regarding the real or supposed virtues of this article to be found in a family here and there in nearly all lands, and not infrequently venerated as a fetich. It is not wise for the physician to ridicule the idea, neither should he encourage the belief that anything bordering on the miraculous attends its use.

The stone certainly possesses virtues, and its value would be enhanced if its use was understood, its limitations recognized and its method of action separated from all thoughts of magic and the superstitious awe which often surrounds it.

There is no particular variety of stone or substance which may be designated exclusively as the mad stone. I have seen many of them, so called, and no two were of exactly the same composition, geologically considered. Mad stones act on the same principle that a blotting paper does when absorbing ink, and there is nothing that makes a better one than baked pipe clay. A new clay pipe, pro curable for one cent at nearly any store where tobacco is sold, can not be excelled by any mad stone, no matter how great its reputation.

The action can be clearly demonstrated by placing a common dry red brick in contact with the margin of a puddle of water and noticing what capillary attraction will accomplish. Therefore, to be efficient, the only necessity is for the stone to be porous and have strong adhesive and absorbent qualities. Nothing mysterious about it. I have seen several that appear to be concretions, either vesical, renal or biliary, and were found in the bladder, kidney or liver of some animal; those taken from the deer, supposed to be the best.

When a person is bitten by a reptile or dog supposed to be mad and the porous stone applied to the wound, the blotting-paper action begins, and the blood, saliva from the mouth of the animal and whatever poison these fluids contain will naturally, by capillary attraction, be absorbed by and into the substance applied, no matter what name you may give it.

The saying that if a stone "sticks" the wound is poisonous, and if it does not take hold there is no venom present, is untrue. If the stone is clean and dry it will adhere when moisture is within reach till it becomes saturated. For instance, a new red brick will absorb one pint of water. After the venom has been taken into the circulation the mad stone is worthless; but as the victim is usually filled with whisky or alcohol at the same time the stone is being used, the spirits may counteract the effect of the poison.

One stone in a certain county of this State has a wide reputation, and makes a

good living for the family owning it. They never let it go out of their sight, and when the victim can not be taken to the stone one member of the family can be hired to take the stone to the victim. In addition to traveling expenses, they charge five dollars for the application and two dollars extra for each hour that the stone sticks. This stone is busy a large part of the time. Not long since the stone "held" to a man's leg for over one hundred hours, yet the man died. His life could have been saved if dependence had not been placed entirely in the stone.

It is true that most of the deaths from the bites of dogs supposed to be victims of rabies are due to fright, and even when the dog is not diseased in any way the mind can be so worked up to the limit of tension on account of stories told by foolish friends and neighbors, who are never lacking, that often fatal convulsions are the result. Hysteria has more than once been mistaken for hydrophobia. True hydrophobia is almost unknown in the human race. Some experienced physicians even go so far as to deny its existence.

[Written for the MEDICAL BRIEF.]

Malarial Fever.

BY JAMES W. DAVIS, M. D.,

Allons, Tenn,

Probably some of the BRIEF family have never tried aconite, digitalis, and gelsemium in malarial troubles; if not, study them a little and give them a trial in your next case. These remedies being poisonous necessarily require some caution in their administration, but when the temperature is 101½° to 103° F., it is time to use the following:

℞ Tinct. Digitalis ..... ½ ounce.
Tinct. Aconite.....5 minims.
Tinct. Gelsemium .....5 minims.
Aquæ.....3 ounces.
M. Sig.: One tablespoonful every four hours.

Bathe with tepid water, containing sodium carbonate, once a day, while temperature is high. Calomel, in one-grain doses, for the first three days, until the tongue becomes clean.

Digitalis increases the circulation, which is almost always lacking in febrile troubles, and is also a heart stimulant.

Gelsemium is a sedative, and must not be given when there are cardiac troubles.

Aconite is cardiac and nerve sedative, and must be administered with caution.

I have used these remedies in persons of tender years, have lost as few cases as anyone, and have them on their feet in half the time my brother physicians do who use other methods.

I do not pretend to say that these drugs are specific in breaking up fever, but I do say that they are specific in their action, and must be given with judgment.

It is astonishing to watch the effect of gelsemium in puerperal fever. I usually give one drop every three hours until patient becomes quiet and cool. I also find it of much value in neuralgia and sciatic affections.

If any brother physician has not given these remedies a trial, I hope he will do so, and then report his experience in the BRIEF, as I know he will have good results.

I wish success to the BRIEF and its many thousands of subscribers.

[Written for the MEDICAL BRIEF.]

A Valuable Alterative Compound.

BY J. A. BURNETT, M. D.,

Dean Spring, Ark.

The following is a valuable alterative compound in most all cases where an alterative is indicated:

℞ Potassium Iodide.....6 drachms.
Fld. Ext. Phytolacca..2 drachms.
Fld. Ext. Echinacea..1½ ounces.
Simple Syrup, q. s....6 ounces.

M. Sig.: Dose, one drachm three times a day.

Many obscure cases that do not readily yield to the seemingly indicated remedy can soon be relieved with this compound. In all cases of chronic sore throat, no matter what the cause is, this remedy is useful. Many forms of skin diseases will readily yield to it. Chronic malaria will soon give way under its action when an antiperiodic is used before a few chill times, in order to keep off the paroxysms, and the liver first being stimulated by a good cholagogue. It is of value for enlargement of the spleen, tonsils, ovaries, lymphatic glands, as well as various other

enlargements. It is an antiscrofulous remedy and systemic antiseptic, a powerful alterative and reconstructant. Can be used in all diseases due to fatty metabolism and retrograde tissue change and the strumous diatheses. Weakly, undeveloped children improve under its use, and weakly, undeveloped girls at the age of puberty are greatly improved or cured by its use.

When used for enlargement of glands, its value is usually enhanced if alternated with the biniodide of mercury, and the same holds good when used for various skin diseases and syphilis. Give this valuable alterative, antiscorbutic, antisyphilitic, antiseptic and reconstructant compound a trial and be pleased with the results.

[Written for the MEDICAL BRIEF.]

Diphtheritic Serum.

BY N. D. TOBEY, M. D.,

Salina, Kansas.

I see in July BRIEF, page 444, an article by Dr. Rose on the antitoxin question, and find that the savants of Germany are taking one and the other by the ears, and German savants have the right to speak *ex-cathedra* on bugs dangerous to the human race. It is a little refreshing to see that they aim to place a new song in our mouths so that we shall sing and whistle the same at their diction, but it soon becomes ridiculous to the thinking medical mind.

If the treatment is given according to the bug theory and the patient elects to die, it is too grave a subject to blame the physician for injecting antitoxin for the trouble, although it does not seem to be indicated. If the patient dies it is no fault of the treatment—only because the patient was too stubborn to live, and the consolation of friends is that he was taken away by devouring bugs, and our serum too late in arriving to save the patient. The lateness of arrival out in the country and remote places is often the apology for its neglect to perform what is claimed for it. From the fact that old serum is to be returned shows that freshness is an essential quality, and even the preservatives can not keep it active for any length of time.

No doubting Thomas dares to venture the suggestion that all that is claimed for the bug theory and their destruction by serums can be proven by results.

We are surely living in a period of great achievements and rapid transit, yet our transit is so rapid that we are dumped off at stations for which we purchased no ticket.

[Written for the MEDICAL BRIEF.]

Sleeping Directions.

BY U. SMITH, M. D.,

Sacramento, Cal.

For all ages, whether two or more in bed, follow the example of hogs, with bodies in reversed directions; then the lung emanations are never inhaled by either. Children should be early taught this, for sanitary reasons; the married should be very observant in this particular. Tubercular and glandular diseases are often communicated by inhalations.

Further, the saliva accumulations during the night are more or less poisonous; therefore, the necessity of a thorough mouth-cleansing before lips are permitted to join in loving friendship.

COUGH.

℞ Syrup Tolu..... 3 ounces.
Misc. Acacia..... 3 ounces.
Tinct. Hyoscyamus..... 1 ounce.
Ext. Licorice Powder..... 1 drachm.
Morphia Sulph..... 4 grains.
Hydrocyanic Acid.....30 grains.

M. Sig.: One teaspoonful three or four times a day.

SCIATICA.

One teacup of celery seed tea just before going to bed. To make: Three or four teaspoonfuls of seed in two cups of water; simmer to one. Sweeten to taste. Avoid acids.

DIARRHEA.

℞ Tinct. Camphor.....1 ounce.
Tinct. Opii.....1 ounce.
Tinct. Rhubarb .....1 ounce.

M. Sig.: One teaspoonful every twenty minutes till relieved, let patient drink all cold water desired. Apply woolen cloths, hot water and ammonia to abdomen. Splendid children's remedy.

[Written for the MEDICAL BRIEF.]

State Board Examination Questions, Michigan State Board of Registration in Medicine, October 9, 10, 11, 1906.

ANATOMY.

1. Describe the chief processes and general characteristics of the humerus.
2. What are the muscles of the forearm?
3. Describe the femoral artery.
4. Describe the collateral circulation after ligature of the common carotid artery.
5. Mention the principal convolutions of the brain. What are the ventricles of the brain?
6. What are the cranial nerves, and what do they supply?
7. Name the subdivisions of the alimentary tract and the accessory organs.
8. What are the lobes and fissures of the liver? Describe the gall-bladder.
9. What is the trigone vesical?
10. What are the muscles of the tympanum? What is the nerve supply to the tympanum?

PHYSIOLOGY.

1. Metabolism. Define and give classification.
2. When can a given amount of starch be said to have been completely digested?
3. Mention and give function of some one large system of veins beginning and ending in capillaries.
4. Give function of liver other than the secretion of bile—and mention varieties of blood found within the organ.
5. Blood. Trace its course through the heart and lungs, beginning at the right auricle. Describe the changes that take place.
6. Describe the function of the stomach.
7. Name all the valveless veins, and state why they have no valves.
8. Give function of kidneys.
9. State function of sympathetic nervous system.
10. Mention four elementary principles essential to health.

HISTOLOGY AND EMBRYOLOGY.

1. Name and describe the various forms of epithelial tissue.
2. Name the elementary tissues of special function.
3. Define and describe the lymphatic circulation.
4. Describe the formation and growth of the nails.
5. Give the structure of Peyer's patches.

CHEMISTRY AND TOXICOLOGY.

1. Define acid and base.
2. What is meant by "valence"? What is the valence of Ca., Na., and K.?
3. How is ammonia prepared?
4. Define the term anhydride.
5. Classify ferments found in the body. Name one member of each class.
6. Give the composition of the gastric juice. Give tests.
7. Give symptoms and treatment of poisoning from bichloride of mercury.
8. Describe opium poisoning. Distinguish between opium and alcoholic poisoning.
9. Describe cocaine poisoning.
10. Give symptoms of poisoning from the continuous use of acetanilide. Treatment.

BACTERIOLOGY.

1. Define bacteria; state methods for recognition, cultivation, and the conditions most favorable for growth, and the different ways of entering the body to produce disease.
2. Give details for the examination of sputum for the tubercle bacillus.
3. Describe method for determining the bacillus of tetanus, and state origin, form, properties and growth.
4. What are ptomains, toxins, toxoids? What is an antitoxin—an antitoxic unit?
5. How would you make a bacteriological examination in suspected diphtheria? State dosage of diphtheritic antitoxin in pharyngeal and laryngeal cases, and in the different stages: also dosage for immunizing or prophylactic purposes.

SURGERY.

1. Local anesthesia. Describe agents and methods.
2. What is sepsis, giving symptoms and stages?
3. Describe the different amputations at the ankle joint.
4. Describe inguinal colostomy, giving indications for same.
5. Give differential diagnosis of dislocation of the femur.
6. Describe the complications of fracture, with treatment.
7. Describe osteomyelitis, giving etiology, differential diagnosis, sequelæ, treatment.
8. Give the surgical consideration of gastric ulcer.
9. Give diagnosis, cause, and surgical treatment of calculus.
10. Give diagnosis and surgical resources of intestinal obstruction.

GYNECOLOGY.

1. Describe the pathological effects caused by laceration of cervix, and all reflex disturbances therefrom.
2. What pathological conditions follow lacerated perineum; their immediate and remote manifestations, and, if operation be required, how soon should it be made, if not immediately following the injury?

3. What is vaginismus, its cause and treatment?

4. What are the sources of streptococci poisoning in the puerperium, and in what per cent of such cases does it occur? How should the local and constitutional manifestations of the disease be treated?

5. What is cystocele? Give symptoms and treatment.

OBSTETRICS.

1. External pelvimetry. Give procedure of taking external measurement, and enumerate the various normal diameters.

2. Tuberculosis. What influence does gestation have on the course of this disease?

3. Mention regulations for diet during normal pregnancy.

4. Give treatment of asphyxia of newly born.

5. Funicular presentation. Give etiology, diagnosis and treatment.

PATHOLOGY.

1. Hyaline degeneration. Give its etiology and seats.

2. What is metabolism in diabetes?

3. Describe the lesions produced by excessive cold and heat.

4. Describe hypertrophy, and give its etiology and pathological anatomy.

5. Describe briefly the general structure of tumors, and discuss their classification.

6. Describe and give the pathology of congenital atelectasis.

7. Distinguish between fibrinous, catarrhal, purulent, and fibrous pneumonia.

8. Give pathology of chronic salpingitis.

9. Differentiate between caries and necrosis, giving etiology and pathological anatomy of the latter.

10. What is osteomalacia?

PRACTICE OF MEDICINE.

1. What are the remote effects of syphilis of the nervous system?

2. Mention some of the more common diseases of the heart; their diagnosis, prognosis, and treatment.

3. Describe pleurisy, both serous and purulent; diagnosis.

4. What is the prognosis in serous pleurisy?

5. What is the prognosis in purulent pleurisy?

8. Give the dietetic management of acute pneumonia, gastrointestinal indigestion, and chronic parenchymatous nephritis.

6. What are the symptoms in gastric ulcer? Differentiate from duodenal ulcer.

7. Describe the characteristic physiognomy in typhoid fever, tetanus and exophthalmic goiter.

9. What is the clinical difference between diphtheria and streptococcic infection of the throat?

10. The cause and treatment of scurvy?

EYE, EAR, NOSE AND THROAT.

1. What is trachoma; its cause; symptoms; course; prognosis; medical and operative treatment?

2. Describe the Argyll-Robertson pupil, and give its significance.

3. Describe the organs of the nerve supply of the function of hearing.

4. What is chronic nasal catarrh—its pathological anatomy, and treatment?

5. Describe the larynx and its cartilages—the laryngeal ligaments and the vocal cords.

MEDICAL JURISPRUDENCE.

1. What do you understand by the term Medical Jurisprudence?

2. A dead body is discovered in some sequestered spot, with or without marks of external violence. How would you proceed to make an examination of said body?

3. Differentiate between wounds inflicted before death, and those inflicted after death.

4. Define insanity from a medicolegal standpoint.

5. What constitutes malpractice?

HYGIENE AND PUBLIC HEALTH LAWS.

1. Define the term hygiene as related to the science of medcine, and state what you understand by health laws.

2. What diseases may develop from the use of impurities in water? Impurities in milk?

3. What deleterious gases accumulate in an imperfectly ventilated school room, and state amount of fresh air required per minute for each child; also state evil effects from the inhalation of air rendered impure by respiration.

4. Name most improved methods of disinfecting living rooms. State what precautions should be observed in typhoid fever, and with regard to the sputum of tubercular patients.

5. What diseases must be reported to the board of health? State fully the duties of the physician as required by our statutes.

MATERIA MEDICA AND THERAPEUTICS.

1. Explain what is meant by empirical use of remedies and their intelligent employment, and give examples.

2. Describe some of the so-called remedies much in vogue during the past fifty years which are now deemed worthless, if not harmful in certain cases.

3. Describe hypnotics, and the two classes into which they may be divided. Give examples.

4. What are anthelmintics? Vermifuges? Vermicides? What are the parasites against which they are directed?

5. What are the physical properties of amyl nitrite? Give its effects and therapeutics.

Book Notices.

AMERICAN PRACTICE OF SURGERY. A Complete System of the Science and Art of Surgery. By Representative Surgeons of the United States and Canada. Editors: Joseph D. Bryant, M. D., and Albert H. Buck, M. D., of New York City. Complete in Eight Volumes. Profusely Illustrated. Vol. I. now ready. New York: William Wood & Co., Publishers. Price, per volume, Muslin, $7.00; Brown Sheep, $8.00; Half Morocco, $8.00.

American practice of surgery differs so greatly from the practice in foreign countries that a work that is thoroughly American should command the attention of all who know how the practice is carried on to-day by progressive methods that are enhanced by American ideas; the peer of all nations in medical and surgical science. It is only within a decade that America has made the practice of surgery the absolute science that we find at the present writing. In this work we have a teacher and an author of wide experience to guide us, and a list of writers of wide reputation to contribute the articles of which this great work is to be composed. The material contained in this work will be entirely original—written for this work alone—and, naturally, embracing much that has never before been published. No foreign writers have been invited to take part in the work, therefore it is purely American. All practitioners need an American work on surgery, and, therefore, should secure this one.

RHYTHMOTHERAPY. A Discussion of the Physiologic Basis and Therapeutic Potency of Mechano-Vital Vibration to Which is Added a Dictionary of Diseases, with Suggestions as to the Technic of Vibratory Therapeutics. With Illustrations. By Samuel S. Wallian, A. M., M. D., President American Medico-Pharmaceutical League, ex-President Medical Association of Northern New York, Member New York State and County Medical Societies, Fellow of the American Electro-Therapeutic Association, Member Medico-Legal Society, Associate Editor Medico-Pharmaceutical Journal, Etc. Chicago: The Ouellette Press.

The busy physician, who is obliged to read as he runs, will appreciate that "Rhythm is the Underlying Law of the Universe;" that the "Music of the Spheres is as Real and Demonstrable as any Law of Mathematics;" that "The Morning Stars have been Singing Together since the Primal Dawn;" that "Life is an Incessant Succession of Rhythmic Reiteration;" that "Disease is the Opening of a Discordant Stop;" that "Death is a Cessation of Vibrant Impulse (It Shuts the Organ Manual);" that "Fate is the Architect of the Organ;" that "The 'Voice of Nature' is the Diapason of the Infinite;" that "Music is Vibrant Harmony—It is Love Struggling for a Language;" that "Love is Music that has Found a Language;" that "Hate is the Clash of Antagonistic Vibrations." And that a work along the lines of the subject of this new therapeutic measure has a deep value to the student of science, as well as the general practitioner. It is a work that will fill in a niche in your leisure time, and you will be the better for the reading.

A TEXT-BOOK OF HUMAN PHYSIOLOGY. By Dr. Robert Tigerstedt, Professor of Physiology in the University of Helsingfors, Finland. Translated from the Third German Edition, and Edited by John R. Murlin, A. M., Ph. D., Assistant Professor of Physiology in the University and Bellevue Hospital Medical College, New York City. With an Introduction to the English Edition by Professor Graham Lusk, Ph. D., F. R. S. (Edin.). New York and London: D. Appleton & Co. Price, $4.00.

The author describes, in this work, in a very lucid and explanatory way, the science of life and the study of the functions of living organisms, also the grand study of the normal, as distinguished from the pathological vital phenomena. The author claims that the discoveries made in the realms of practical medicine, of experimental pathology, and of pharmacology, which, in many respects, are so full of significance for the processes of the body, are, therefore, for the most part passed by, at a sacrifice for what some consider more important facts. There are so many good things in this work that we almost forgot to lay stress on the great number of excellent illustrations that adorn its pages. When illustrations are made accurate and explanatory, it is of the greatest importance to the elucidation of

the text. Altogether, this translation of Tigerstedt's text-book of physiology is, to our notion, the most complete and most broadly conceived one for its size in any language.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene, and Other Topics of Interest to Students and Practitioners. By Leading Members of the Medical Profession Throughout the World. Edited by A. O. J. Kelly, A. M., M. D., Philadelphia, with the collaboration of Wm. Osler, M. D., Oxford; John H. Musser, M. D., Philadelphia; Jas. Stewart, M. D., Montreal; John B. Murphy, M. D., Chicago; A. McPhedran, M. D., Toronto, Canada; John G. Clark, M. D., Philadelphia; J. W. Ballantyne, M. D., Edinburgh; Edmund Landolt, M. D., Paris; Thomas M. Rotch, M. D., Boston; James J. Walsh, M. D., New York; John Harold, M. D., London; Richard Kretz, M. D., Vienna; with regular correspondents in Montreal, London, Paris, Berlin, Vienna, Leipsic, Brussels, and Carlsbad. Vol. III., Sixteenth Series, 1906. Philadelphia: J. B. Lippincott Co., Publishers. Cloth, $2.00.

Are you a subscriber to the International Clinics? If not, your library is not complete, and you are not looking for the best in medical literature. The best medical lights of the profession are contributors to the pages of this work, as you can plainly see by a glance at the above. It contains some of the best articles and illustrations of any work that comes to our table; therefore, it deserves just such mention as an unbiased mind should give it. Give it a thought, and rely on our judgment.

THE PHANTOM OF THE POLES. By William Reed. New York: Walter S. Rockey Company. Price, $1.50.

At the present writing Peary has arrived at the nearest point to the North Pole, yet there seems to be some reason why he could not *absolutely* reach it. This work gives an idea that should any of the adventurers reach the pole they would find an opening into the center of the earth, and find continents, oceans and rivers, and, perhaps, a class of people yet unknown to surface residents. As no one has yet been able to reach either pole, why not conceive of a continent on the inner surface, as well as the outer? The question is open to the discoverers, and why is it so difficult to get the facts? It seems that the best talent, the most courageous people that inhabit our outer globe, have used their best endeavors to discover the poles, yet they signally fail to accomplish it. Why?

The book is worth reading, as it gives you ideas on a mooted question—the kind of ideas we are looking for.

A TEXT-BOOK OF HISTOLOGY. By Frederick R. Bailey, A. M., M. D., Adjunct Professor of Normal Histology, College of Physicians and Surgeons, Medical Department, Columbia University, New York City. Second and Revised Edition. Profusely Illustrated. New York: William Wood & Company. Price, $3.00.

The principal aim of the writer has been to give to the student of medicine a text-book of histology for use in connection with laboratory instruction, and especially to furnish to the instructor of histology a standard manual for classroom teaching. To obtain these two objects the text has been made as concise as possible, without sacrificing clearness, and the more essential elements have been emphasized sufficiently to make them stand out somewhat from the details which necessarily accompany them. Dr. Bailey's long experience has most eminently fitted him for the task of writing such a work. We commend it to all advanced thinkers on the subject.

BUFF. A Tale for the Thoughtful. By a Physiopath. Boston: Little, Brown & Co., Publishers. Price, $1.00.

The title of this work would suggest the idea that it is a fictitious novel, but far from it is its teaching, as it is a work that views life, medical theories, and practice, from the standpoint of nature—it shows a disposition that the methods of nature, *per se*, are superior to man's methods. A careful diet and plenty of fresh air is the restorative power of nature, as shown by a careful reading of this work. The author aims to furnish a correct basis for obtaining a perfect physical endowment, and what could be best suited for the thoughtful reader in the prevention and cure of disease in all its stages.

Editorial.

Don't Whine.

If a mining promoter sells you stock in some mining property, of which you know nothing regarding the actual value, and the stock turns out to be worthless, with the result that you lose your money, don't whine—but remember next time to find out something definite as to the value of what you are asked to buy. In the same way, if a druggist sells you an imitation of some standard proprietary remedy, and it fails to accomplish what you have come to expect from the original preparation, with the result that you lose your patient, don't whine—but learn your lesson with good grace, and resolve not to be gold-bricked in the future.

A Mistake.

We have before us a circular issued by the St. Louis Retail Druggists' Association, in which doctors are told not to prescribe proprietary remedies; a pamphlet is inclosed, giving a number of imitation preparations for the use of physicians in prescribing. It is our belief that a mistake has been made in this matter, as doctors will surely resent this impertinence on the part of the druggists, in telling them what to use and what not to use. The formulas sent with this circular are intended to be substitutes for long-established proprietary preparations, whose value has been proven during years of use by the profession. Now, the Editor of the BRIEF was a retail druggist for seven years, and from his experience in the business, together with what he learned as a country doctor, a village doctor, and a city doctor, he knows it is an impossibility for the retail druggist to successfully imitate the standard proprietary preparations. Such an attempt is purely guesswork, and the result is not "the same thing" and "just as good" as the original; the chief objection being that the substitute does not accomplish

the results the physician has come to confidently expect from the original remedy. The doctor's first duty is to his patient, not to the druggist, and we believe he will continue to prescribe what he has found to yield the best results, regardless of the edicts of self-appointed instructors. Our idea is that this is a scheme on the part of certain druggists to trick their competitors into thinking it unnecessary to keep a full stock of the well-known proprietaries regularly prescribed by physicians. Knowing that good doctors will refuse substitution on the remedies ordered for their patients, this clique of druggists are evidently counting on increasing their business by means of this stratagem. They well know it is the height of presumption for a druggist or anyone else to dictate to the doctor what drugs he shall use.

The Man of Independent Mind.

The business of the physician is to heal the sick. When he is called into a case, that should be his only aim and purpose, to accomplish which, if he is a sincere and practical man, he will use those agents which he considers most effective for the end in view. And it does not make any difference to him whether they are simple home-made remedies or are intricate products of chemistry.

One can not withhold admiration from the patient worker who, after long and laborious search, has evolved some new chemical, but the amount of labor or skill expended in its production bears no relation to its remedial value. But right here is where the profession is often led astray. A new discovery is made. Some new chemical is brought into existence. And the very fact of novelty lends to it an interest out of all proportion, and sometimes, without regard to its value as a medicine. It is "featured" in the medical and the lay press. Medical societies discuss it at their meetings, and members detail their experiences with it. The reports of these experiences are, from the nature of the case, in most instances favorable, for the minds of the experimenters were prepossessed in favor of the remedy before they began to use it, and hence they are easy to convince. They write papers for the medical journals about it, and these papers are copied into other journals, and so it goes. There is so much talk about it, that more and more physicians get to using it, and in a short time it comes into almost general use—it gets, in fact, to be a medical fad, and without its having ever been fairly and thoroughly tested. And all because its discoverer or creator happened to be a man of high-sounding reputation, or because the big chemical house in whose laboratory it was evolved was shrewd enough to "work" the profession and the medical journals under the guise of science. Admiration for art and skill has blinded the judgment to the one practical question: *Is it a good remedy?*

We hear a good deal about ethics these days. We are told that it is not ethical to do this, that or the other. That we must not use one remedy because some pretender has pronounced it unethical. That we *must* use some other because it *is* ethical. Now, ethics relates to morality, and, as such, it should influence and direct our every act. But it can have nothing whatever to do with the selection of a remedy. *This latter is a practical question.* It can not be decided according to any theory, but only on proof *supplied by facts.* If the evidence proves that it possesses certain medicinal virtues, that should settle the question. And so it *does* with the man of *independent mind. He* laughs at the vagaries of the pretenders. He does not care a fig if Doctor So-and-So says a certain remedy or method of treatment is not ethical, or if some other doctor says it *is* ethical, but he asks himself these simple questions: *Will it do the work I want it to do? Will it benefit my sick patient?* And after deciding these questions, according to the lights before him, he uses the remedy or discards it, and without regard as to whether his action meets the approbation or the censure of some other physician who has wrapped about himself the mantel of self-importance and presumes on his right to dictate to those whom, in his egotism, he *imagines* are his social and professional inferiors. Bobby Burns was right when he said:

> The man of independent mind,
> He's king of men for a' that.

Some Practical Hints in Prescription Writing.

BY J. S. CASSIDY, A. M., M. D., D. D. S.,
Professor of Chemistry and Materia Medica in the Ohio College of Dental Surgery.
Covington, Ky.

Materia medica is that part of therapeutics which includes the study of the origin, physical and chemical nature, therapeutic and toxic effects, local and general, of materials employed for the cure, alleviation, or prevention of disease.

Although it is not often incumbent on the dentist to prescribe medicines for internal administration, it is proper that he should know the general effects, dosage, incompatibles and antidotes, when so exhibited, of those drugs which he uses in his practice as local agents, inasmuch as a majority of them are active poisons.

By knowing these effects, he can make judicious selection and combination of materials for any prescription that, in his judgment, will best suit the case in hand. He would not, for instance, order a combination of any soluble chloride with silver nitrate, or any vegetable astringent with per salts of iron; or use, even topically, excessive quantities of arsenic, or tincture of aconite root, etc.

The art of writing proper prescriptions is a serious labor to the average student. If we could prevail upon him to discard completely the signs and symbols of the old systems of weights and measures, and adopt the metric system, exclusively, he would find the task much easier; and if, as occasionally happens, he should be deficient in knowledge of the Latin language, he should take courage and realize that very few Latin phrases are needed in prescribing.

In writing a prescription containing a number of substances it is proper to place the most important article in the combination, first, as the basis; the adjuvans, or assistant to the base, next; the corrective (if the first two have certain objectionable properties—as taste or smell—) comes next; and, finally, the vehicle to give form and elegance to the whole.

In writing prescriptions, according to the metric system, the only signs needed are Gm. and f. Gm., and fractions of them are stated decimally, in the same way that we write our divisions of Federal money. Both systems of weights and measures, however, should never be used in the same prescription, as is sometimes done.

The percentage of solutions can be made in prescribing according to the metric system, taking the gram as the unit of weight, and the f. gram as the unit of measure.

Carelessness, in chemical nomenclature, leads to many mistakes in prescription writing, as a mere change in termination of names, like "mercuric" and "mercurous," as the one, would indicate the presence of corrosive sublimate, etc., and the other would be practically harmless. These two illustrations are sufficient to

indicate the danger of using chemical names.

One more important point: The importance of writing prescriptions in a legible hand, and unless this is done the prescription may not be accurately filled. Making all due allowance for haste, etc., there is no reason why all prescriptions should not be written in a good, readable hand.

[Written for the MEDICAL BRIEF.]

Some Notes on the Practical Treatment of Diabetes Mellitus.

BY E. R. HEATH, M. A., M. D., F. R. C. S.,

Professor of Pharmacy in the Eclectic Medical University of Kansas City.
Kansas City, Mo.

The first thing to do in the treatment of diabetes is to keep up the strength of the patient. There is no special diet except to restrain patients from using what they themselves (from experience) know will injure them. In the more serious cases of diabetes where there is grangrene or carbuncles, the intense thirst can be relieved at once by giving cubes of granulated sugar or pieces of maple sugar every half hour; push it. The general lesions in diabetes is a lesion in the floor of the fourth ventricle. That is the starting point, or origin, of the splanchnic nerve, and an irritation at that point will produce an extra flow of urine. There are conditions where the pneumogastric nerve is so irritated by this irritation in the brain that the digestion is interfered with and uric acid is formed in large quantities. That also can be treated by forcing the carbohydrates. The liver and portal system often are almost paralyzed, and in the analysis of the urine the guide to the condition of the diabetic patient is the amount of phosphates in the urine. In severe cases the phosphates entirely leave the urine, and as soon as they can be brought back the patient begins to improve.

The amount of sugar in the urine is of no consequence. It is simply a phenomenon, a symptom, that is all. Whenever a disturbance of the portal system occurs, it also communicates itself to the pancreas. At those times the pancreas will be enlarged and the secretions that are thrown into the intestines by the liver and the pancreas are intensely corrosive acid. To neutralize these conditions we require remedies for the brain rather than the digestive organs.

To test the urine with litmus paper does not reveal its condition, but by administering the permanganate of potash solution a few drops of urine will bleach the color almost immediately, although the blue litmus paper will not show acid reaction.

One of the best remedies in this condition is phosphoric acid. I mean homeopathic phosphoric acid; the use of uranium nitrite is limited to a very few cases, and only useful where the uric acid is intensely prominent. Calomel and remedies to start the bile oftentimes will break up some cases of diabetes. However, one must be very careful not to use too much cathartic. In cases of gangrene the wounds should be dressed with powdered red Peruvian bark; one grain capsules of red Peruvian bark is also useful to take internally at that time.

Where the rheumatic pains are excessive in cases of severe diabetes, rhus aromatica is the best remedy. There are some twenty conditions of diabetes mellitus. Certain skin diseases will produce it, and, consequently, remedies to relieve that condition may be useful. Some cases can be directly traced to vaccination. Among the starchy foods potatoes, except raised in a cold country like Colorado, are very harmful in diabetes; they can take other starchy foods without any reserve whatever and to the alvantage of the patient.

When patients have an odor of acetone or diacetic acid they are in danger of coma, and then we must press the carbohydrates; but good cider vinegar made into vinegarade just after meals will help the digestion and break up the formation of diacetic acid and acetone. When the acetone is very prominent and marked, hydriotic acid will break up the acetone condition and change it to an aldehyde, and that existing, forms acetic acid, which is normal digestion.

Syphilitic Diseases of the Nervous System.

BY GEORGE OGILVIE, B. SC., M. B. (EDIN.), M. R. C. P. (LOND.),

Chevalier de la Legion d'honneur; Senior Physician to the French Hospital, London; and to the Hospital for Epilepsy and Paralysis, London. London, England.

I.

The division of syphilitic symptoms into primary, secondary, and tertiary, is a legacy left by Ricord of very doubtful value, as it has been a constant source of confusion, and a cause of much dogmatic and arbitrary handling of clinical facts. The principle upon which the distinction was made by Ricord—that only the primary stage was infectious by contact, the secondary only infectious by heredity, and the tertiary not infectious at all—has been given up by every one. The same fate has befallen the other nosological difference introduced by him between secondary and tertiary symptoms, viz., that the former only affected skin, mucous membranes, eyes and scrotum, while the latter attacked the inner organs. Those who, after Ricord, have tried to put this division of syphilitic symptoms on a different footing, do not seem to have been happier than he was. The pathological scheme (Virchow) of dividing the symptoms into irritative and neoplastic, is no better than the clinical scheme (Zeissl) of dividing them into papular and gummatous; again, the division of symptoms (Auspitz) into acute and chronic, has as many shortcomings as that (Reder) into exanthematous and metastatic. Others have tried to avoid these difficulties by placing upon all these modes of dividing the symptoms of syphilis a chronological meaning, corresponding to earlier and later, and limiting the earlier period to from two to three years after the appearance of the primary sore. Those who seem to rely upon time only as a distinction (Finger) have, however, always introduced, in addition, some clinical characteristics of the two sets of symptoms following the primary sore, such as benignity, spontaneous recovery, universality, symmetry, etc., and, consequently, we are told that the secondary stage may extend considerably beyond the time arbitrarily fixed upon as its limit, and we are also told that the latest (tertiary) symptoms not unfrequently appear during the earlier (secondary) stage. In fact, with regard to some "tertiary" lesions, we are led to the paradox that they are most common in the "secondary" stage.

Not one of these different divisions or classifications is fully satisfactory, still each of them contains a kernel of truth. They all aim at giving expression to an undeniable fact, that in the ordinary course of syphilis a clinical difference exists between those symptoms which accompany and closely follow the eruptive stage, and those which, after a period of latency, appear later on.

As a consequence of the infected state of the blood, Hutchinson teaches us that secondary symptoms are almost always symmetrical, while in the tertiary stage, the virus having ceased to exist in the blood, we ought not to expect the phenomena to be either general or symmetrical. Later, I shall have to refer again to the fact that the nervous affections show no more tendency to symmetry during one stage than during the other. Here, however, I should like to draw attention to the odd consequences to which this forced classification of facts must necessarily lead. Interstitial keratitis in hereditary syphilis is, according to Hutchinson, in the end always symmetrical, as well as the deafness frequently associated with it. Both these affections appear, as a rule, at the age of puberty, but occasionally much later. Still, their constant symmetry seems, according to Hutchinson, to prove that they really belong to the secondary group. Consequently, we would have here a secondary period, extending over considerably more than ten years. No one will maintain that during this period hereditary syphilis remains, either infectious or transmittable, and still the secondary stage was defined as being that during which the blood is infected, and as coincident with that during which contagion and hereditary transmissions are possible. Here, theory and fact come into conflict, and in trying to stretch the latter so as to fit the former, a

contradiction arises which can not be solved.

Perhaps, in no chapter of our knowledge of syphilis has this confusion been more apparent than in the study of syphilitic diseases of the nervous system. It is perfectly true that in a great many, even, of our modern text-books the teaching is that they are the latest manifestations of the disease, and that the rare exceptions are to be regarded as precocious cases. This erroneous doctrine is not due to want of valuable investigations to prove its fallacy, but to the difficulty of getting rid of heresies once accepted as facts and covered by Ricord's great name. In fact, during the last quarter of a century numerous observers have shown that the first two years after the infection exhibit an extraordinary predominance, as far as the development of nervous affections is concerned, over any similar period during the whole course of the disease. They prove that nearly one-half of all the nervous affections met with in syphilis appear during the first two years. I am not speaking here of casual observations of early nerve disease —observations which might be traced as far back as forty years ago and more, and which have given rise to the teaching of "precocious" nervous symptoms—but of systematic statistical compilations of observations made by different men at all stages of the disease. Only these latter are of importance, as they enable us to form a definite idea as to the place which a single symptom holds in the picture of the disease.

For a long time syphilis of the nervous system has been considered the prototype of what is called tertiary syphilis. But the inadequacy of the time-sanctioned division of syphilitic lesions into secondaries and tertiaries is, perhaps, nowhere more apparent than when applied to nervous diseases. Originally, the division was evidently made from a purely chronological point of view, and the difference between secondary and tertiary symptoms amounted to nothing more than a distinction between earlier and later manifestations of the disease. But Ricord already had, with this chronological principle, interwoven an anatomical, or rather, a topographical one. Affections of the skin, throat, pharynx and nose, iritis, carcocele, etc., were, according to him, counted secondaries; and affections of the bones, the muscles, the liver, the brain, etc., tertiaries. Virchow, justly exposing the weakness of this ambiguous classification, replaced Ricord's anatomical point by a pathological one. Not the seat of its lesion, but its nature, became with him the decisive moment. The inflammatory processes became the secondaries, the gummatous the tertiaries. Such a division was a decided progress, compared with its predecessor. But, in application to clinical experience, it also proved a procrustean bed, into which the unwieldy form of the disease can not be forced without considerable distortion of facts. For not only the inflammatory and gummatous changes are frequently combined, but also some of the latest affections of the nervous system may be purely inflammatory, while the gumma may appear at the very onset of the disease. I will not relate other attempts at classification which have been made in order to avoid the shortcomings of those just mentioned. None of them have found such a general acceptance as these two, and none have succeeded in putting the multiplicity and irregularity of the manifestations of this "most regular" disease upon a more satisfactory footing or basis. The principal defect of the usual classification is its hybrid nature—the intermixture of two or even more distinct principles of division. But while aware of the unsatisfactory and inadequate character of this generally accepted classification, we are looking out in vain for something better. If we consider what we understand by the term tertiary, as distinct from secondary, we will find that by the latter we think of some early inflammatory infection of the skin or mucous membrane, while the former brings into one's mind some late gummatous affections of the bone or brain. In other words, we will find that the three different principles just mentioned, viz., the chronological, the anatomical, the pathological, are mixed up together. If the result is not satisfactory, the fault lies with the principle of classification, or rather, with the unruly disease, which baffles all attempts at orderly arrangement. As I have said,

this is most apparent where syphilis of the nervous system is in question.

Of late, our views with regard to the time of onset of nervous diseases in syphilis have undergone a complete change. Formerly, brain and spinal cord were considered the parts last to be attacked by the syphilitic virus. Careful statistics, however, show that while the first year after infection furnishes a very large proportion of cases of nervous diseases, it is the first two years, taken together, which produce considerably more than half of all the nervous diseases to be observed in connection with syphilis. Two, or even three, years is now the duration generally allotted to the secondary stage. It follows, therefore, that the majority of nervous affections in syphilis belong to the secondaries, or what is generally called so.

It is generally granted that there is no nervous disorder characteristic of syphilis. Of course, there are certain features —the multiplicity and transitoriness of the symptoms, the proneness to relapse, etc.—which will favor the diagnosis of syphilis. But even these, syphilis has in common with *non-syphilitic* nervous diseases, such as hysteria and multiple sclerosis. On the whole, there is not a single clinical criterion by which we can with any degree of certainty declare an affection of the nervous system to be syphilis. Consequently, our diagnosis rests on three points:

1. A previous history of the disease, or traces of past or present syphilis.

2. The possibility of excluding other causes.

3. The effect of anti-syphilitic treatment.

With regard to the *first* point there is the possibility of a double fallacy; that everything found in a syphilitic is not necessarily due to syphilis; secondly, that the absence of all evidence with regard to syphilis, past or present, does not in any way disprove the syphilitic origin of the nervous disease. The *second* point is of a still more intricate nature. With the unsatisfactory state of our insight into the etiology of nervous disease in general, the inability to find some other plausible explanation for the existence of some nervous disorder, amounts to a confession of the limitation of knowledge, rather than to the "exclusion" of other possible causes. Moreover, it is rare to find cases in which a careful and complete examination of a patient's general health, hereditary tendencies, habits, etc., fails to reveal some other condition which might have had a noxious influence upon the nervous system. And, with regard to the *third* point, my belief is that the diagnostic value of the so-called specific drugs is considerably overrated; for not only are we constantly open to the old *post hoc propter hoc* fallacy, but also many nervous diseases, whether syphilitic or not, may greatly improve, and even disappear without any treatment, specific or otherwise. And we must remember that the inefficiency of the treatment proves nothing against the syphilitic nature of the complaint, while, at the same time, it seems quite unlikely that the efficacy of such powerful drugs as mercury and iodide of potassium should be limited to one particular disease. Those who, for diagnostic purposes, rely upon the effect of "specific" drugs, will make grave mistakes. With regard to mercury, it will be generally admitted that its curative effect extends beyond the domain of syphilis. To the preparations of iodine, on the other hand, an almost exclusive action is ascribed by many. Statements of this kind always invite a close scrutiny of the evidence upon which they rest. If we take the rough-and-ready routine treatment of organic disease of the nervous system of *doubtful* origin, it consists, first and foremost, in the application of anti-syphilitic treatment. According to general usage, its efficacy is admitted as sufficient proof of the syphilitic nature of the disease. If, relying on this principle, we adduce such cases as proof of the specific effect of the drug, we are moving in a vicious circle, and I feel sure that many of the statements with regard to the so-called specific action of these drugs rests on such false reasoning. Of course, where all three points can be satisfactorily established, *i. e.*, where there is clear evidence of present or past syphilis, no concurrence of other etiological factors, and a speedy or more or less complete recovery under specific treatment, the diagnosis can, *intra vitam*, be made with

a probability, practically amounting to a certainty. Even then mistakes are possible. But cases in which all these conditions are fulfilled are comparatively rare. If one goes carefully and critically through the profuse literature of the subject, closely examining the evidence given, one is struck by the levity with which the diagnosis of syphilis is frequently made. If there were such a thing as the Scotch verdict, "not proven," in syphilography, syphilis of the nervous system would shrink surprisingly. The statement, for instance, that tertiaries of the nervous system are more frequent than tertiaries of other organs, is explainable by an individual experience, or, perhaps, by an indiscriminate and hasty procedure in diagnosing syphilis.

We must add that, even histologically, the diagnosis of syphilis of the nervous system can not be made with absolute certainty from the anatomical appearance alone. We know that in syphilitic diseases of the nervous system the nerve substance remains primarily intact; that the changes which it undergoes are secondary to gummatous growths, meningeal exudations, and vascular alterations which disturb its nutrition. But these changes are, one and all, *not* pathognomonic. The gumma, the obliterating arteritis, once considered as truly specific, have, with the progress of histological research, lost this claim.

A casual connection between syphilis and a nervous disorder can not be established by the report of isolated cases, but only by the consideration of a large number of cases of the same kind. This difficulty of diagnosis is further increased, if we turn from the syphilitic diseases of the nervous system to those called parasyphilitic. With an Apollonian *"Inventum medicina meum est,"* Fournier proclaims himself the "inventor" of parasyphilis. Indeed, the numerous contributions to the subject which have followed the publication of his work in 1894 seem to be more or less *μιᾶς φωνῆς πολλαὶ ἀντανακλάσεις*—the re-echoings of his powerful and far-reaching voice. Thus to discuss the principles of the doctrine and its bearing on retrospective diagnosis and treatment, means nothing else than to discuss the principles laid down and the conclusions drawn in Fournier's writings. I am, therefore, justified in closely following and limiting myself to his line of argument. Dr. Edmund Fournier's book on the same subject I shall treat as one of his father's, as he himself declares, *que son père en reste l'inspirateur et l'auteur anonyme.*"

A parasyphilitic affection is defined as one syphilitic in origin, but not in nature. Its two characteristic features are the following:

1. Parasyphilitic affections are to be met with independently of syphilis; they may be due to other causes as well; they are banal, while syphilitic lesions, properly so called, such as mucous patches and the gumma, are never produced outside the domain of syphilis.

2. The so-called specific drugs, *i. e.*, mercury and iodide of potassium, have a totally different influence upon parasyphilitic affections from that which they are known to exercise upon true syphilitic lesions.

"There is really an abyss between the one and the other." These drugs are said to have either no effect at all upon parasyphilis or the effect is slow and incomplete, while in the case of syphilis proper, it is "rapid and efficient." "These two principal features," according to Fournier, "seem to establish a well-marked line of demarcation between syphilitic affections proper and the so-called parasyphilitic ones."

If, from a clinical point of view, the specificity of the mucous patch and the gumma has to be granted, there still remains among true syphilitic lesions a great many which, to use Fournier's own words, are "banal and borrowed from ordinary pathology." As such he, himself, mentions the disturbances of the general health, fever, anemia, asthenia, wasting, cachexia, etc., as well as aches and pains, neuralgia and neuroses, which have nothing specific besides their origin. He also mentions rashes of the skin, so similar to, and so much resembling, common rashes that the most expert dermatologist is unable to differentiate between them. But the list of non-specific, yet truly syphilitic lesions, is by no means exhausted. Hutchinson has made the remarkable statement that all the

various phenomena of disease due to syphilis are imitations of other non-specific type forms. "We have," he says, "absolutely no malady which is peculiar to syphilis." Without going so far, it will have to be granted that, apart from those mentioned by Fournier himself, numberless affections, such as iritis, choroiditis, hemiplegia, paralysis of single nerves, transverse lesions of the spinal cord, etc., present nothing specific, apart from their origin. Nobody would think of excluding all these manifestations of true syphilis from the domain of syphilis proper under some other name for the sole reason that they are "banal." Moreover, there is among those who grant the specificity of certain syphilitic affections a great diversity of opinion regarding the affections deserving of such a distinction, viz., to be considered pathognomonic. Take, for instance, interstitial keratitis. I believe that, notwithstanding the statement just quoted. Hutchinson does not hesitate to base the diagnosis of inherited syphilis on this symptom alone. It is the same with the notched teeth which go by his name. And with regard to either symptom, he has many convinced followers. According to Fournier, and perhaps the majority of syphilographers and ophthalmic surgeons of our time, both symptoms are to be met with in other diseases besides syphilis; they are "banal." Interstitial keratitis is, to some, nothing but an expression of impaired nutrition, to others, as frequently, of tuberculous as of syphilitic origin.

Leucoderma is given by Fournier as the classical prototype, the type par excellence of a parasyphilitic lesion. On the other hand, I. Neumann, of Vienna, says that there exists at present only one opinion, viz., that leucoderma is absolutely characteristic of syphilis. Very few, I believe, will not subscribe to this statement. Opinions are, likewise, divided with regard to ophthalmoplegia externa, to the skin infiltration of the newly born, to certain forms of choroiditis, to spastic spinal paralysis, etc. On the other hand, it seems that at least one parasyphilitic lesion does not deserve the designation "banal," if one is to go by the frequency with which syphilis can, according to Fournier, be proved in its previous history, *i. e.*, tabes. He has found that of thirty-six observations in reference to gumma of the palate, forty-four per cent were without a syphilitic history. He confesses that this proportion is extraordinary and unusual, and taking into account the possible error caused by what he calls "*la chance des séries*," *i. e.*, the accidental similarity or identity of a number of consecutive cases —he proposes to reduce it, and even to diminish it by one-half—a reduction on a most extraordinary scale, considering the probability of such serial sequence. That would still leave twenty-two per cent without a syphilitic history. Syphilis is a cause of tabes, according to Fournier, is present at least nine times out of ten, *i. e.*, there are less than ten per cent without a history of syphilis. If one takes into consideration the mental state of some of the patients on whom we have to rely for their previous history, "without mentioning all the cases of syphilis abnegated or willfully concealed, of syphilis overlooked or unnoticed, also the cases of conceptional hereditary syphilis," one would scarcely be surprised to find the final figures on the other side of a hundred, in the same way as the addition of certain mortality statistics leads to figures in excess of the birth-rate. I may be allowed to remark that from my own experience, which extends over more than one hundred and forty hospital and no small number of private cases, I am personally convinced of the important part which syphilis plays in the production of tabes without, however, going to extremes or even believing that the question has been finally settled. Different observers, from different parts of the world, have pointed to the non-existence or infinite rarity of tabes in districts where syphilis rages endemically. At the first glance this seems to be a very strong argument against the specific origin of tabes. Yet it has to be borne in mind that exactly the same has been reported with regard to other affections, which in our climes, at least, are undoubtedly a frequent consequence of syphilitic infection, such as diseases of the eye. How far functional use or "irritation" influences the localization of the noxious effects of the syph-

ilitic poison, we do not know. With the present state of our knowledge we must confess that certain facts in the pathology of tabes are only with great difficulty, if at all, reconcilable to the doctrine of its syphilitic origin. Anyhow, it seems strange to call an affection "specific" which, in its antecedents, lacks evidence of syphilis in from twenty-two to forty-four per cent, while another should be "banal" with less than ten per cent. I am not aware that this strange contradiction has been pointed out before, much less that it has been satisfactorily explained.

In his recent careful and interesting statistics of tertiary syphilis, Neisser gives the percentage of those who present tertiary symptoms without a history or evidence of previous infection at about fifty. How can it, then, be explained that an affection like tabes, which, after all, belongs to the late sequelæ of the disease, should, in its previous history, afford evidence of syphilis with such astounding frequency? The only explanation which presents itself to my understanding is that some seekers after syphilis will seek and find even an "absent argument." For general paralysis, the percentage is, by several authors, given as high as for tabes. The obvious consequence would be that the disease can not be called "banal." Banality, one of the "characteristics" of parasyphilitic affections, is, as we have seen, not an attribute of all of them, while it is an attribute of numberless syphilitic affections. Which particular affections are to be considered specific, which "banal," is, after all, to a large extent, a matter of personal opinion. Anyhow, the most banal of lesions may be and frequently is syphilitic.

With regard to the second "characteristic"—the influence of specific drugs—it must be admitted that this seems only a question of degree. Of course, in many syphilitic affections, the effect of mercury and iodide is "at once intense and rapid." But I am not going to enumerate all those in which it is slow, little or none. Quite apart from cases of idiosyncracy to the drugs, or cases of malignant syphilis, one has only to think of the many disappointing results in cases of hemiplegia choroiditis, ophthalmoplegia, spastic spinal paralysis, etc., to realize the incongruity of making the effect of the drug a criterion of the nature of the disease. On the other hand, it is not generally admitted that specific drugs are powerless in leucoderma, tabes and general paralysis. Good results have been reported in general paralysis and in tabes which, unfortunately, I have never been able to obtain. Fournier, himself, has had most satisfactory results, amounting to complete cures, in cases of parasyphilis, where one would expect them least, viz., in certain heredo-syphilitic dystrophies, and he advocates mercurial treatment in most cases in which parasyphilitic affections are met with in children only suspected of heredo-syphilis. "Those who think that the result of treatment by specifics may be relied upon as establishing the diagnosis, may easily make great mistakes. Syphilitic affections often resist treatment for a long time (I may add, even altogether) and, on the other hand, mercury and iodides often effect the greatest possible good in cases which are not syphilitic" (Hutchinson). How, then, could a "characteristic" of this kind be of use in drawing a line of demarcation between two classes of affections, supposed to differ in nature? Later on, I shall have to say a word on the "nature" of parasyphilitic affections in general. Of the arbitrariness which must, of necessity, reign in allotting a certain disease to one of the two classes of affections, I want to give at least one instance. Interstitial keratitis, according to Fournier, is not necessarily syphilitic, an opinion in which I concur. All will agree that, if at all, it is neither rapidly nor intensely influenced by drugs. Its course may be shortened and attenuated, but on the whole it is an affair of many months, whether treated by specifics or not; it is never cut short by them, and with the most energetic treatment, is often extremely tedious. Yet this affection, bearing both the characteristics of parasyphilis, is not classed under the latter. This example conclusively demonstrates that either of the two criterions, taken singly or together, is utterly unfit to decide anything respecting the nature of the disease. Take, for instance, a case of spastic spinal paralysis, or of choroiditis (both "banal" affections)

of undoubted syphilitic origin, as proved by the co-existence of such specific lesions as a gumma, which latter disappears under specific treatment, while the paralysis, or the choroiditis, remains little or not at all influenced. Such cases abound. Was the "banal" affection syphilitic or parasyphilitic? It was, of course, syphilitic, although it bore both the characteristics of parasyphilis, viz., banality and refractoriness to specific treatment. The classical type of parasyphilis will, after all, be a scar left by some ulcerative syphilitic process, for instance, an ulcerative gumma. Here we have a lesion of undoubtedly syphilitic origin, and possessing the qualities of banality and refractoriness to treatment. If one were to object that a scar can not properly be called an "affection," it has to be remembered that the terms "affection," "stigma," and "lesion," are all through used promiscuously by Fournier. A scar certainly is a stigma, and intra-uterine amputation stumps or dental erosions are no more "affections" than scars are. But there seems no need for inventing an extra name for a scar left by a pathological process, nor can anything be gained by huddling together distinct pathological processes, as, for instance, pneumonia, corneal ulcer, etc., when due to the same cause, *e. g.*, measles, under the denomination of parameasles.

With regard to the parasyphilitic affections following acquired syphilis, I shall have to say only a few words. The connection of tabes and general paralysis with syphilis seems to me established by carefully and critically sifted clinical evidence. Nothing of the kind can be said of any other parasyphilitic lesion attributed to the acquired disease, such as neurasthenia, hystero-neurasthenia, hysteria, epilepsy, etc. Of course, in a neurotic person syphilis may, and will, like any other disease, play the part of *agent provocateur*. In this way syphilis will be responsible for many manifestations of the variegated disease called neurasthenia. But so will gonorrhea or a cold, or any other complaint befalling a neurotic person. To give an idea of the degree to which syphilis may react on the mind and, consequently, on the nervous system, Fournier cites the case of a young man who, on being told that he had an indurated chancre, immediately went home and hanged himself. Of course, suicide here seems parasyphilitic *par excellence*, although parasyphilis at a remarkably early stage. Its syphilitic origin is beyond doubt, it is eminently "banal" and past cure.

A similar event has quite recently been reported by another eminent syphilographer in a case of gonorrhea. It would seem odd to describe it as paragonorrheal, yet there is, apparently, no reason why the frequent and profound disturbances of psychical functions, following this disease, particularly in its chronic stage, should be treated differently from those caused by syphilis. In the new "Traité de Syphilis," by Fournier, the functional disorders of the nervous system during the secondary stage are treated at considerable length. Here they are described as syphilitic, and specific treatment is urgently recommended as the only and certain remedy. In his book on parasyphilis, the identical nervous disorders are treated at the same length, and the complete inefficacy of specific treatment is given as proof of their parasyphilitic nature. It seems that exactly the same nervous complaint during the same stage may, in his opinion, be either syphilitic or parasyphilitic, either only curable by specifics or not at all. That strange symptom boulimia, as a manifestation of syphilis, although by no means unknown in the country of beef-eaters, appears in the "Traité" as a syphilitic disease, the symptom of a "diathesis, which requires the treatment necessary for that diathesis and nothing more." In the work on "Parasyphilis" this very same boulimia appears (in a foot note) as a parasyphilitic affection, the characteristic of which is not to yield to specific treatment. Evidently, we are to understand that during the secondary stage of syphilis there is a boulimia syphilitic, and apart from it a boulimia parasyphilitic, both affections "banal," the one curable and curable by mercury alone, the other not amenable to mercurial treatment. Such incongruities are the natural outcome of the capricious principle underlying the whole division between syphilitic and parasyphilitic lesions.

My conclusions may be summarized as follows:

1. Syphilitic diseases of the nervous system appear most frequently during the first year after the infection, that this frequency decreases from year to year, and that within the first year they seem to be a little more frequent during the first than during the last six months.

2. The relation between cured and uncured cases is nearly the same between the ages of twenty and twenty-nine as it is between the ages of thirty and thirty-nine, and also very nearly the same as for the total number of cases. After the fortieth year the prognosis becomes somewhat less favorable.

3. As long as the nervous disease appears within about ten years after the infection, it is of very little moment whether it appears early or late. After the interval of ten years the prognosis becomes less favorable.

4. It is irrelevant, as far as the prognosis is concerned, what time has elapsed since the last syphilitic manifestation, as long as the interval does not exceed ten years. After the tenth year the prognosis becomes decidedly more unfavorable.

5. The prognosis is considerably more favorable in cases with early treatment, viz., before the end of the first four weeks. After the first four weeks cures are considerably less frequent.

[Written for the MEDICAL BRIEF.]

Ringworm and Its Treatment.

BY A. WINKELRIED WILLIAMS, M. B., C. M. (EDIN.), D. P. H. (LOND.).

Physician to the Skin Department Royal Alexandra Hospital for Sick Children.
Brighton, England.

No. I.

The subject of ringworm is always of interest and often, unhappily, of distress to practitioners of medicine, to parents, and to teachers. The uncertainty of results of treatment in scalp cases, the peculiar obstinacy of the fungus in some children, have led to such serious delay in their education that the subject is one of great national importance. The recent improvement in the methods of using X-rays, and the great success of this treatment *when available*, makes the present time a suitable one for a general review of the disease and its treatment.

Readers of the MEDICAL BRIEF will remember the paper by Dr. Blaxall* relating to the various fungi causing ringworm. The study of this subject is a curious chapter in the history of medicine, a chapter illustrating confusion and forgetfulness on the part of physicians, dermatologists and pathologists working on the subject between 1843 and 1893.

In 1843, Grüby described the fungus of small-spored ringworm, but his work was neglected and forgotten until Sabouraud published his work on the varieties of ringworm.

The work of Sabouraud was accompanied or followed by a host of other investigators, prominent amongst whom are Adamson, Blaxall, T. C. Fox, Malcolm Morris, Leslie Roberts, and others. A huge variety of fungi have been described, many of which are sub-varieties produced by differences in mode of culture.

The following table includes the maximum number of varieties that can be said to have clinical significance:

Ringworm.
- Small spored fungus (microsporon audouini.)
- Large spored fungus.
  - (a) Trichophyton megalosporon endo-thrix.
    - (1) Resistant.
    - (2) Fragile.
    - } Mycelium.
  - (b) Trichophyton megalosporon ecto-endothrix.

CHARACTERISTICS OF ABOVE VARIETIES.

I.—MICROSPORON AUDOUINI.

Common type of scalp ringworm of children, rare in adults, occasionally found in domestic animals. Rarely infects children after the age of fourteen years. Body patches usually insignificant. Most extremely contagious. Scalp lesions usually obstinate.

Scalp Lesions. (1) *Onset Progress.*—Small, red papule about orifice of follicle, spreads peripherally and scales develop, the hairs lose gloss, look dusty, become thickened, lose elasticity and then break off.

(2) *Fully Developed Untreated Patch.*—Distinctly circumscribed, round or oval shape, reddish tint, peripheral red ring, scalp slightly raised at patch. Usually a dirty, scaly look, crusts. Patch studded

* MEDICAL BRIEF, August, 1897.

with hair stumps, which are surrounded for a short distance above the skin with asbestos-like collarette.

Glabrous Skin Patches.—Generally confined to head and neck, but may be universal. *Type A.* Commoner, small, irregular, scaly patches; slight redness. *Type B.* Raised red rings, with double contours; sometimes a second ring inclosed in first. Spread centrifugally.

Microscopic Examination. (1). *Hair from Early Patch.*—Few large spores and perhaps a loose meshwork of large, peculiarly transparent mycelium scattered over shaft. Hair cuticle intact.

(2) *Further Advance.*—Mixture of large and small spores, large and small mycelia; hair cuticle loosened and separating or separated in places.

(3) *Fully Developed Stump With Collarette.*—A sheath of small spores extends from just above junction with bulb to some distance up shaft; no definite arrangement in the closely-packed double-contoured spores. A mycelial fringe extends below sheath. Septa in mycelia irregularly placed and generally far apart. Above the complete spore sheath are situated here and there irregular masses of spores. Below spores on surface of shaft a mycelial meshwork extends upwards to broken end of shaft.

Natural History.—After infection giant spores form on surface of hair, then giant mycelium penetrates and develops as a meshwork inside root sheath. From the giant mycelial threads fine shoots (*haustoria*), grow out and pierce cuticle and secrete a kerato-solvent matter which digests and strips cuticle from hair shaft. Then a fine meshwork of mycelia closely envelops shaft from which small spores rapidly develop, and form spore sheath, and the giant spores disappear.

II.—TRICHOPHYTON MEGALOSPORON ENDOTHRIX.

It is doubtful whether the *two types*—resistant and fragile mycelium—are really different species of fungus.

General Clinical Features Common to Both Types.—Infection may occur in much older children than in case of microsporon. It is, however, less virulently contagious, and generally less obstinate. The scalp patches are cleaner than microsporon. They are smoother, and not raised and covered only with broken hairs and stumps. Body patches common, usually small, well defined, raised, red and scaly. Beard and nails not attacked.

Microscopic Appearance Common to Both Forms.—Larger size of spores. Spores inside hair. Arrangement of spores in lines, giving string of beads or ladder-like appearance.

III.—TRICHOPHYTON MEGALOSPORON ENDOTHRIX AND RESISTANT MYCELIUM.

Clinical Features.—*Scalp patches* generally smaller than microsporon; few or numerous patches. Some cases with no distinct patches; only groups of stumps; scattered stumps and black dots; usually a general seborrhea-like scurf.

Microscopic Appearance of Hairs—Early Stage.—Strings of jointed mycelium, and spores outside hair. *Fully developed.* Inside hair are long mycelial rows, more or less broken up into spores. Many spores are square (ladder-like look of row of mycelial spores). Some spores separate and are rounded or oval. A mycelial fringe stretches down at bulb. Mycelial threads larger than microsporon.

IV.—TRICHOPHYTON MEGALOSPORON ENDOTHRIX WITH FRAGILE MYCELIUM.

Clinical Features.—Found at times in adult scalp. *Scalp Lesions.*—Patches, when present, are more or less rounded, size variable, surface generally smooth and bald (resemble alopecia areata). Patches sometimes so small and scattered that disease is unnoticed. Hairs are often found in scattered groups of stumps or stumps isolated and scattered over scalp. The stumps are very short and so fragile that epilation may be almost impossible.

Microscopic Appearance.—Fully Developed in Hair.—Entire hair filled with big spores, spores rounded, arrangement in strings distinct in places; in other parts difficult to recognize. Mycelial fringe at bulb. Cuticle usually present, not easily recognized in much smashed hair. This type of ringworm is often diagnosed as alopecia areata.

Trichophyton Megalosporon Ecto-Endothrix. Clinical Features.—No marked age limit. Often communicated from lower animals to man. Causes parasitic sycosis,

ringworm of nails, majority of cases of pustular ringworm, and eczema marginatum.

Hairy Parts.—Begins as ring of papules, vesicles form in papules and then become pustules, vesiculation and pustulation not necessarily marked; crusts often form, with a red, oozing surface below. Hairs often not broken, except in old cases, and even then stumps are relatively long. The hairs are often matted down in the crusts, hairs are loose. On extracting hair, a well-marked sheath is seen on the epilated hair. The sheath does not project above the level of skin as in microsporon.

Body Surface.—Begins as small, red macule or papule, or often first seen as a scaly red patch. Peripheral spread, the center often becoming normal, but not always, it may remain less red, but still scaly; it may remain pustular, margin usually pustular. In animal communicated cases the whole patch may attain full size, and be uniformly composed of pustular points.

Microscopic Appearance.—Hair.—Spores often not much larger than in microsporon, and look like them in the external sheath. They form round hair. Cuticle of hair is usually not stripped off, but it can not always be clearly recognized. Hence, clinical features or culture test must decide the question of type, more than microscopic appearance.

The cultural appearance of the different varieties depend much upon the medium, etc., and so are not of great clinical value. The main point of practical interest is that on a medium, such as beer wort agar at 30° C., microsporon ringworm appears as a visible growth in nine to ten days. The large-spored fungi grow much quicker, a visible growth appears in three or four days.

A study of the therapeutics of ringworm may be approached from, firstly, *the pharmacological side, i. e.*, a consideration of the various drugs used in its treatment, their action upon the tissues, upon the fungus causing the disease, and upon the morbid matter produced by the fungus. From, secondly, *the clinical side*, by a consideration of the special regions of the body attacked by the ringworm fungus, and the treatment applicable to each region. From, thirdly, the *public health side*, the modes of limiting the spread of the disease in schools and other communities.

It is unnecessary to give details of the *pharmacology* of the remedies used in ringworm. They may be classified as follows:

FIRST—*Agencies of Value in Cleansing the Skin from Debris, e. g.*, soap, water, spirit ether, ether and alcohol, fixed oils, kerosene, turpentine, chloroform, potash, soda, etc. Also various mechanical methods, as hair clipping, shaving, epilating (mechanical and X-rays), curetting, etc.

SECOND.—*Applications used to attack the Ringworm Fungus.*—Various antiseptics, starving out the fungus, disinfectants, destroying the more superficial fungus.

THIRDLY.—*Applications Used to Modify and Alter condition of Soil on Which the Fungus Grows.*—(a) *Reducing agents, i. e.*, drugs removing oxygen from surface of epidermis and increasing keratin formation, which in the scalp tend to hasten the development of the adult condition. Most of these reducing drugs also act as antiseptics and disinfectants, *e. g.*, resorcin, chrysarobin, ammonium sulpho ichthyolate, sulphur, etc. Also mechanical methods of *endeavoring* to exclude oxygen, *i. e.*, plasters, solutions of gutta percha, collodion, etc.

(b) Attempts to desiccate the skin, *e. g.*, alcoholic sprays, abstinence from water washing, etc.

(c) Drugs of value in removing coexisting diseases, *e. g.*, seborrhea, the presence of the seborrhea products increase the virulence or vitality of the ringworm fungus.

(d) Drugs causing inflammatory or other reactions of the skin, with the products of which the ringworm fungus may be cast off, *e. g.*, croton oil, common salt, X-rays, etc. Most of the disinfectant drugs act this way, notably iodine, tar, carbolic acid, turpentine. Also mechanical methods, by friction, pressure, rough, epilation, especially epilation by plasters, epilating sticks etc.

FOURTH.—*General conditions raising physical state of patient.*

FIFTH.—*The Vehicle by Which Active Drugs Are Conveyed to the Skin of the Patient.* (1) Watery solutions or suspensions (to be used after a preliminary removal of grease from the surface by soap, ether, etc.).

(2) Spirit.

(3) Collodions, traumaticin, plasters, etc.

(4) Fatty substances. These are the most generally used and usually the most valuable on account of their penetrative action, *e. g.*, lard, mineral oils, liquid animal (whale) or vegetable oils. Probably lanolin, with a softening addition of a liquid oil, is the best; its penetration power is considerable. Oxidized mineral oils, *e. g.*, valsol and vasogen, are highly praised on account of their penetrating power, but the author's experience of these vehicles has been disappointing. The most useful form is six per cent iodine vasogen; this, in a few cases, caused a pustular perifolliculites followed by an easy extraction of the entire hair and a rapid cure, but in many cases no result followed, while in a few instances, where the child had an idiosyncrasy to iodine, its application was followed by great pain, lasting for several hours, with production of bullæ, without marked loosening of the hairs.

Aniline oil has also been praised by some; it certainly takes active drugs through the epidermis, but can only be used on a small area and applied only for a minute or two, or alarming and dangerous symptoms of aniline poisoning result, with cardiac failure and cyanosis. The author's experience of this medium leads him to warn practitioners to try any other method in preference.

THE STUDY OF RINGWORM FROM THE CLINICAL SIDE.

Regions to Be Considered.—

The scalp.

The nails.

The beard.

The axillary and crural regions.

The body general.

The Scalp Region.—Great difficulties are met with in this region, and authorities are not in unity on many details, notably:

1. Washing.
2. Cutting hair or shaving.
3. Value of mechanical epilation.
4. Relative value of drugs.
5 Vehicle for application of drugs.
6. Safety or danger of X-ray treatment.

The following notes may help to solve some of these questions:

Great care is necessary in soap and water washing or infection will be spread, especially when large areas of previously untreated ringworm exist on the scalp. The patches must first be cleansed from surface debris, etherial antiseptic soaps, etc., are useful; curetting and rough epilation, after oiling surface, may be necessary. The scalp is then washed, some authorities recommend soft soap; the author uses a one per cent to three per cent biniodide soap. After washing, careful drying is necessary, and a dabbing and not a rubbing movement of the towel used. Drying must always be *immediately* followed by application of an antiseptic to the entire scalp. The above method of washing is impossible with long hair, shaving scalp or clipping hair is, therefore, necessary, leaving, at the utmost, a narrow peripheral band of longer hair. The author recommends shaving in the early stage and clipping in the later stages, when it is important to examine hairs to decide whether they are sound or diseased.

The following are suitable antiseptics for use after washing:

1. A spray of strong solution of sulphurous acid.

2. A spray of one-half ounce eucalyptus oil in ten ounces spirit.

3. Oiling with salicylic acid in oil.

4. One drachm precipitated sulphur in one ounce of olive oil. This is the author's favorite. Its only objections are (1) it somewhat hides the scalp, (2) it produces, especially when mercurial applications are used on the patches, a dirty look at border of scalp. The former difficulty is avoided by a visit to the patient at end of scalp washing, and the latter is a temporary inconvenience.

5. Carbolic acid in glycerine (one in eight). This is a favorite with patients and it is useful, as it does not hide the scalp, but during its extensive and regu-

lar use it is advisable to examine the urine and stop its use at the first indication of albuminuria.

Epilation, excepting in cases where hairs are loosened by inflammatory and pustular processes round the follicles, is only a partial process, on account of the easy fracture of the hair shaft, leaving in the deeper part of the follicle an injected stump. It, however, removes a large amount of infective matter and leaves for a few minutes a gaping follicle into which antiseptic ointments can be more easily rubbed.

In kerion and such pustular affections, loosening the hair in follicle epilation is of intense value. In kerion, the author's experience shows the value of epilation, giving, if necessary, an anesthetic and, after epilation, boroglyceride is a valuable application. It is quite a mistake to wait until the hairs fall out.

The author's routine in ordinary ringworm is as follows:

1. Short clipping or shaving scalp.
2. Cleansing the patch. (a) Rub on a little antiseptic ointment and with forceps epilate roughly the patch. (b) Cleanse it from debris by ethereal antiseptic soap and rub it with turpentine.
3. Wash head with biniodide soap and apply sulphur and oil over entire scalp.

The above treatment to be applied once a week. In interval, use antiseptic ointments rubbed well in, twice daily, and once a day apply the sulphur oil to entire scalp, and about twice a week apply to patch, after cleansing with ether, one drachm carbolic acid, and one ounce of acetic acid. This application must not be used indiscriminately or sloughing of the skin may be produced.

In later stages, Aldersmith's croton oil treatment is largely used.

The internal administration of small doses of arsenic and iron often helps in obstinate cases. The doses are not large enough to produce edema of the deep layer of epidermis, or to be eliminated with the hair cells, and its exact action is difficult to explain, but the author has frequently seen cases which were at a standstill in non-anemic children commence to improve directly this internal treatment was added to the local treatment.

[Written for the MEDICAL BRIEF.]

Squint and Ocular Paralysis.

BY EDWARD LUCAS HUGHES, L. R. C. P. (LOND.), M. R. C. S. (ENG.),

Fellow of the Royal Institute of Public Health; Late Ophthalmic Surgeon to the Hope Street Hospital. Liverpool, England.

There has always been in medicine a sort of warfare between empiricism and science, and nowhere has this been more the case than in the realm of the pathology and treatment of squint. Empiricism has had such an advantage, owing to ignorance of the true nature of the subject, that it is only of recent years the subject has become placed upon a firm scientific basis, and even now the immediate brilliant results of operations upon the recti muscles seem, at first sight, to confirm past erroneous ideas, and to militate against the true scientific explanation of the facts. The path of science is slow, tedious and often extremely difficult; the human mind desires a short cut, a royal road to immediate success. Empiricism offers that royal road by substituting blind action, based upon the jumping at wrong conclusions, and as Professor Edgar Browne puts it, "It frequently obtains an apparent victory over science, because it offers the bribe of a cure, rather than the labor of investigation." Our patients are waiting, and whether we have been taught the right thing or the wrong, whether our reasons for action are scientific or not, there is aways an intense desire on the part of the prompt and practical surgeon to do something, and, indeed, circumstances have nearly always been such that he has not been able to wait for slow, but sure paced, science to overtake him.

The fundamental mistake in the past has been to regard squint as a deformity of the ocular muscles, a purely mechanical displacement, due to anatomical conditions, a supposed shortening, for instance, of an internal rectus muscle, producing a turning inwards of the eyeball, *i. e.*, convergent squint. Tenotomies for the cure of this supposed deformity have been performed galore, in many cases with immediate brilliant results, thus

seeming to prove the deformity idea, but the ultimate results of many of these operations, even cosmetically, have been far from satisfactory. The operation for many years was the admiration of the profession, and surgeons enthusiastically benefited, as they thought, almost every child they encountered that was seen to have a "turn in its eye." Boys are said even to have been brought in from the street to the hospital by enthusiastic operators, and tenotomy, principally that of the internal rectus, was all the rage. That the victory of empiricism over science, as regards this operation, is likely to prove ephemeral, may be shown by a typical case in point.

A man, forty-four years of age, amblyopic in the right eye, shows a slight external squint. He has crossed diplopia, which bothers him sometimes, especially when his accommodation is relaxed. The history is that when six years of age he was operated on for convergent squint of the right eye. At the age of twenty he consulted an oculist, who prescribed glasses for his hypermetropia. The amblyopic eye had +6 D of hypermetropia, with about 1 D of hypermetropic astigmatism, and there was about 3 or 4 D of total hypermetropia of the left eye. He had not worn glasses before the age of twenty. The oculist urged him to again have the internal rectus cut, since even then he had some amount of convergent squint. He, however, refused and decided to wait and see what glasses would do for him. The eyes became straight and the glasses were then altered by another surgeon to a much stronger pair, much more of the latent hypermetropia being corrected, the anisometropia and astigmatism of the right eye being attended to. These glasses, with a slight modification, have been worn ever since, the vision of his right eye has decidedly improved, but there has developed a tendency to divergence, and he shows a sunken caruncle. The divergence, as well as the shrunken caruncle, are both due to the operation of his childhood. What would have happened if there had been a repetition of his tenotomy when he was twenty years of age? Certainly there would have been an extreme divergent squint.

Advancement of the opposing muscle has largely superseded tenotomy of late years, but this is merely shifting the burden from one shoulder to the other, as whether the leverage of one muscle is lessened, or the leverage of the other increased, the result is the same. We must not be biased by the facility of an operation, or the brilliancy of its immediate results from endeavoring to ascertain what are the reasons why the muscles behave in a seemingly abnormal manner. So long as we regard squint as a muscular deformity, and attempt to remedy it by forcible readjustment of the tendinous attachments, so long are we dealing with effects and not causes, and we are, in spite of all improvements in the measurements, ocular movements, and in the details of surgical procedure, still living in the era of Dieffenbach, and followers of his teaching.

The history of strabismus is interesting. Stromeyer and Dieffenbach were practically the pioneers of the modern operative treatment of squint. To them is due the devising of an operation something like our modern tenotomy, but as far back as the seventeenth century, a surgeon named Taylor suggested operation. His attempts were like those of Dieffenbach, in that they consisted in dividing the fleshy part of the muscle and not the tendon; however, they were abandoned, as they were unsuccessful. In the early part of the nineteenth century Stromeyer began to perform myotomy, not tenotomy, upon the cadaver, but it was not until the year 1839 that Dieffenbach began to perform his myotomy operation upon living patients, and introduced it into practical surgery. When he announced, in 1840, to the French Academy of Science that he had cured at Berlin many cases of squint, French surgeons of the time, Roux, Velpeau and Sédillot, commenced to practice the operation, but with utter want of success. It needed Philips, Dieffenbach's pupil, to come to Paris to show them how his master operated "the aponeurosis (Tenon's capsule) was largely separated, and the sclerotic denuded for about a third" (Bérard, article on "Strabismus," in the Dictionary of Medicine, 1844). The ultimate results of this practice were, however, found to be very bad,

causing secondary strabismus, retraction of the caruncle and exophthalmos. A great advance was made when Bonnet of Lyons introduced cutting the tendon, instead of dividing the muscle, showing, after an excellent study of Tenon's capsule and the muscular insertions, that to cut the fleshy fibers was altogether unnecessary. Von Græfe has generally been given the credit of suggesting tenotomy, but the French assert that the honor of its very first introduction belongs to Bonnet of Lyons.

It was another Frenchman, Jules Guérin, who first thought of the operation of advancement. He thought of it as a remedy for a secondary divergent squint, the result of an unfortunate tenotomy for convergent strabismus, this occurring so frequently in his day. Subsequently, George Critchett (*Medical Times and Gazette*, 1857), Liebreich de Wecher, and others, caused the operation to become generally known. Landolt has shown that excellent results may be obtained in a very bad case by an advancement performed upon the two eyes. Squint is not, as is commonly thought, an affection of a single eye; it really affects both eyes. One eye is the apparently good, *i. e.*, the fixing eye, according to circumstances. If the squinting eye is made to fix, which can be always done in recent cases, its fellow will be seen to squint in the same manner and degree. This is called secondary deviation. Some cases are known as alternating squint, each eye taking its turn to do the squinting, while its fellow is performing the duty of fixation. The vision of both eyes, in these cases, is generally good, and there is some amount of the fusion faculty. About the time that Donders was doing splendid work, in showing the relationship that existed between accommodation and convergence, and the rôle that errors of refraction frequently played as an important contributing factor in the etiology of strabismus, George Critchett, of Moorfields, was introducing great improvements in operative technique. This attracted a great deal of attention, but it had the unfortunate effect of preventing Donder's theory, diverting attention from the muscles, as the latter undoubtedly would otherwise have done. Thus, because of operative brilliancy, in spite of science, the false and antiquated muscle idea has continued to live, although Donders gave what, in the future, must prove ultimately its death-blow, by laying firmly the foundation of our modern conceptions of squint. With him began a new era, for he gave a scientific explanation of the occurrence of squint, but it is a mistake to suppose that nobody before Donders had questioned the idea of squint being a muscle affection. A hundred years before Dieffenbach, as far back as 1743, Buffon contended that it was a functional and not a mechanical trouble, but he was not able to bring forward clear mathematical and scientific reasoning for his contention, as Donders has done. M. de la Hire, and many others before Dieffenbach, possessed far sounder and more scientific views concerning squint. De la Hire believed that the squinting eye deviated because the most sensitive part of its retina happened to be away from the path of the optic axis, and that it was for the purpose of adjusting objects which were fixed by the other eye that the squinting eye took up a wrong position. He put; as it were, the cart before the horse, made the effect the cause, since what may be described as the eye trying to rig up as a sort of "jury macula" (false macula) is the effect of convergent squint and a late manifestation when fixation of the squinting eye is lost. However, it shows that even in days long ago scientific minds, unbiased by operative brilliancy, were not at all satisfied with mechanical ideas concerning squint, and, indeed, they were groping after the light we now possess. It is to Dr. Emil Javal we owe much of our knowledge concerning the true nature of squint, besides much light thrown by him on its rational and now operative treatment. In his "Manual of Strabismus," published in Paris in 1896, he brought forward evidence to prove the value of stereoscopic exercises, bar reading and other orthoptic exercises for the eyes. Parinaud, three years later, wrote an excellent treatise on the subject. Indeed, much of the good scientific work has been done by the French, whereas English and even German minds have been satisfied with operative technique, to the neglect altogether of non-operative

treatment. Recently, however, Professor Edgar Browne and Dr. E. Stevenson, of Liverpool University, published an essay on the subject, which is so good that it seems a pity there is not more of it. The second edition of a larger work was published a year ago by Mr. Claus Worth, who shows the importance of the faculty of fusion in regard to binocular vision. He has invented a special kind of instrument which he calls an amblyoscope. It is valuable and, in many instances, accomplishes its purpose, that of the fusion of images seen through its two tubes, and thus the cultivating and developing of binocular vision. The instrument is something more than a mere variety of stereoscope.

Operation can not restore binocular vision; it has been well known for years past that vision is not improved by operations on the muscles; it can only improve matters for the artist and the admirer of beauty; it can not cure the amblyopia. Whereas fusion training and orthoptic exercises preserve vision, prevent amblyopia, develop the fusion faculty and gradually, in a physiological manner, do all that operation can be expected to do cosmetically, without the risk of any ill effects. It is true that operative interference is called for in bad cases where other means have been neglected or have failed, that there are several serious obstacles to success in the non-operative treatment, but on the other hand, those obstacles are not insurmountable, and the fact remains that the ideal and scientific treatment of many squint cases is not operation, but cultivation of normal binocular vision. Judicious operative procedures at the most favorable time are, undoubtedly, useful sometimes, but there should always be beforehand, along with an intelligent appreciation of the true pathology of the affection, an attempt to bring about, by patient perseverance in optical measures, an amelioration of the underlying functional conditions. Dr. Parinaud strongly condemned senseless operative interference. He writes: "I am far from denying that great improvements have been realized in the surgical treatment of strabismus, but it is a mistake to wish to reduce its treatment to a mere question of operative technique. Precision should be sought, on the one hand, in acquiring a deep knowledge of tne pathology of strabismus and, on the other hand, in the analysis of the mode of action of our operations. It is manifest that in directing our operations against a muscular affection that has no existence, we have done up to now what we have never meant to do. How can precision ever be found in a path thus manifestly a wrong one?"

To summarize the object of this paper is to emphasize the value of the non-operative treatment of squint in children. I do not condemn operations in their proper sphere, which is entirely that of improving appearances later on in life after the mischief to the vision of one eye has been done. Amblyopia is the worst thing about squint, worse than the deviation, which is bad enough. Operation may cure the latter, nothing but the proper exercise and development of binocular vision in childhood can cure or prevent the former. Cases have to be taken in time, before the vision has become too impaired. The more important part, therefore, of the treatment of squint is non-operative, and the operative is, although important in its proper sphere, later, and of secondary value.

Many cases of squint depend upon the failure to properly blend together the two retinal images to form one in the brain—*i. e.*, the fusion faculty. There is a lack of development of this faculty which is purely psychical, and the relative misplacement of the eyeballs does not show any anatomical changes in the ocular muscles.

The non-operative treatment of squint consists of exercises by means of the amblyoscope, the stereoscope, bar reading, the covering of the "good" eye, the instillation of atropine drops into the good eye, bimanual drawing, and other measures of value, including the correction of any error of refraction.

[Written for the MEDICAL BRIEF.]

Clinical Diagnosis of Early Syphilis.

BY GEORGE P. CRUME, M. D.,

Professor of Dermatology and Genito-Urinary Diseases in the Medical Department of Hamline University.
Minneapolis, Minn.

During the last decade of the fifteenth century, syphilis made its appearance in Europe. Through the interchange of geographical discovery and international traffic, its spread was rapid and extensive; severe epidemics occurring. These visitations attracted attention, and we find much reference to it in the medical literature of that period.

But the origin of syphilis is, undoubtedly, far more remote, symptoms scarcely to be distinguished in the descriptions from those of syphilis, are described in the ancient literature of several nations, and in the sacred writings of the Hebrews.

Pathological changes in the bones, supposed to have been caused by lues, have been found in the skeletons of prehistoric man.

In spite of the fact that syphilis is not only one of the oldest diseases to which man is heir, but one of the more common, in spite of the fact that a large number of our ablest medical men have devoted much study and consideration to this disease, the cause of many of its manifestations remains unexplained.

The quality of the venereal ulcer was not generally recognized and accepted until the latter half of the nineteenth century, and even to-day the mixed sore occasions much obscurity and some mistakes.

In this paper I shall follow the device of Ricord, dividing syphilis into three stages, realizing that this division is purely artificial, but hoping that it will serve to make statements more clear.

The first stage begins at the moment of inoculation, and ends with the first appearance of the exanthem; the second stage begins with the eruption and continues for one or two years. The third stage includes all manifestations occurring after two years, and is usually referred to as late syphilis.

The symptoms of syphilitic diseases are evolved in a determinate order, and by considering its manifestations from the moment of infection we can best grasp those points by means of which the diagnosis is established.

The acquired disease, excepting, perhaps, conception syphilis, always begins with a chancre, which appears invariably at the point of inoculation, after a characteristic period of incubation—the average and most frequent duration of which is twenty-one days. The limits of this incubative period are from ten to seventy days, never less than ten days. The resulting chancre points to an infection within the month preceding its appearance, and during that time there is no evidence of disease unless the chancre was preceded by some morbid condition. There is no single lesion, the appearance of which invariably signifies that a chancre is present.

Induration is nearly always present in the initial lesion, and is the most distinguishing feature of the chancre. It is usualy evident in five to ten days after the first appearance of the chancre, and varies greatly in degree, sometimes hardly appreciable to the touch, while again, it may have a woody or cartilaginous feel. The degree of induration varies with the location of the chancre, and the accidents of its environment, and gives rise to the different types of primary lesion.

A common form of the initial lesion, uncomplicated with purulent infection, is known as the superficial erosion. It is circular or oval in shape, with an eroded, raw-looking surface, having a thin, serous or sero-purulent exudation, or it may be covered with grayish membrane.

A simple form of initial lesion is called the dry, scaling papule. This varies in size from a pea to a bean, and is brownish red in color, with a slight amount of induration.

In the Hunterian chancre, induration is especially marked; endarteritis occludes the blood vessels supplying the central part of lesion, and a coagulation necrosis occurs, causing a depression in the center, which is funnel-shaped, or like the crater of a volcano. Sometimes there is a very superficial layer of infiltration lying immediately under the skin. It

feels like a piece of stiff paper, and is called a parchment chancre.

True ulceration does not occur in the primary lesion without a mixed infection. The ulceration resulting from coagulation necrosis has sloping and adherent edges, not undermined, and does not extend to periphery or induration. The chancre is not a destructive sore and, as a rule, is not followed by a cicatrix; the ulceration resulting from endarteritis is in newly-formed neoplastic tissue, and from it no scar, or very little, results.

The chancre is not auto-inoculable, consequently we have, as a rule, a single lesion, unless more than one abrasion was present at time of infection, in which case we may have two or more developing at same time.

Adenopathy is an invariable accompaniment of the primary lesion, becoming manifest in from five to ten days after the appearance of the chancre, and always in those lymphatic glands in closest anatomical relation to the chancre. The glands vary in size from a buckshot to a pigeon's egg, are firm and hard in character, freely movable under the skin, not painful, and very rarely suppurate.

Another important step in determining the character of a suspicious sore, is the examination of the individual from whom the patient acquired the lesion, as to the presence or absence of syphilis.

The primary lesion is often a trivial sore, causing little pain, and disappearing in two or three weeks. When a severe lesion occurs and treatment is not applied, it may last several months.

The average time that elapses from the appearance of the chancre until the eruption is seen is forty-two days; the limits of this secondary period of incubation are from two weeks to six months. During this time the blood is becoming saturated with the virus, and frequently we find certain prodromata preceding the secondary manifestations. The most constant are anemia, due to destruction of the red-blood cells; lassitude; rheumatic pains in the bones and muscles; headache, which occurs toward evening, becoming more severe at night, and is not relieved by ordinary remedies; erythem of fauces; fever, the evening temperature reaching 100° to 101° F. During this time the adenopathy is becoming more marked and more general, and is the most common symptom of the secondary incubative period.

This brings us to the consideration of the phenomena of the second stage, and has to do more particularly with the eruptions of skin and mucous membranes. The cutaneous manifestations depend upon two distinct pathological conditions —one the hyperemia, and the other the cellular infiltration. Both of these changes are present in every eruption; in the earlier ones, the hyperemia is more marked, the later the cellular infiltration.

Syphilis is known as the great imitator, and its eruptions may very closely resemble those of almost every well-known skin disease; there are, however, certain characteristics of the eruption, taken as a whole, which will generally make a diagnosis possible. The general features of early syphilitic eruptions (those occurring in the first six months) are as follows:

1. They are superficially seated and generally distributed over the body, appearing first upon the chest and abdomen.
2. They develop slowly, and are not attended by subjective sensations.
3. They are symmetrical.
4. They are polymorphous; macules, papules, pustules, often being present at the same time.
5. They tend to disappear spontaneously by absorption.

The features of the late secondary eruptions are as follows:

They are more deeply seated, often involving the whole thickness of the skin and subcutaneous tissue.

While they may be generally distributed, the relapsing eruptions are never so numerous as the earlier ones.

They are less apt to be absorbed, but tend rather to break down and ulcerate.

The color of the eruptions is by no means characteristic. The early erythema is usually a dusky red, and disappears entirely under pressure; as the lesions grow older more pigmentation occurs, and they cease to entirely disappear under pressure. The color is commonly likened to that of an old copper cent, or the lean of raw ham, but such changes are common

in chronic inflammations of the skin due to other causes.

The eruptions may be classified according to the usual order of their appearance, as follows:

Macular syphilide, commonly known as syphilitic erythema or roseola. This is usually the earliest and most common lesion of the skin. It makes its appearance about forty-two days after the chancre, or nine to ten weeks after the infection. Hyperemia is the marked feature of this eruption, which consists of numerous rounded or oval ill-defined spots, varying in size from a split pea to a ten-cent piece, or larger. They are not elevated above the level of the surrounding skin. Their color is, at first, a rose red and, later, a brown shade. Cooling of the surface makes the eruption more conspicuous. It appears first upon the chest and abdomen and flexor surfaces, and gradually becomes general. It reaches its height in one or two weeks, and lasts from four to six weeks, without treatment.

The diagnosis of the macular syphilide is much simplified by the presence of concomitant signs of the disease. At this time the remains of a chancre are usually present, general adenopathy is evident, and we may find slight fever, angina and mucous patches.

Papular Syphilide.—The lesions of this eruption appear as hard, accuminate or flat, rounded elevations, varying in size from a pinhead to a ten-cent piece, and are classified as the small or large papular syphilide. The small papular syphilide is usually an early manifestation of constitutional syphilis, occasionally preceding the roseola. The papules may be conical, rounded, flat, or umbilicated, and vary in size from that of a pinhead to that of a split pea. At first rose red, later becoming coppery in color. This eruption is usually well marked and involves a large surface.

The large papular syphilide may be conical or flat. The large conical papules are usually discrete, few in number, associated with the small papules, and are most abundant on the back, glutæal regions, calves, and exterior surface of the arms.

The large, flat papules vary in size from that of a split pea to a five-cent piece. The borders are sharply defined and the lesion elevated above the surrounding skin, firm in consistence, and present a scaly or smooth, shining surface.

These lesions usually occur in the middle and latter part of the secondary stage. They may be widely distributed or grouped in certain regions, as the back, nape of the neck, flexor surfaces of the extremities, mucus outlets, the forehead, and surfaces that are in coaptation or are moist. The presence of papules on the forehead, along the hair margin, constitutes what is classically known as the "corona veneris." The papular syphilide, owing to certain changes, may become either the moist papule or the papulo-squamous syphilide. The moist papule is peculair to syphilis, and develops ordinarily from a dry papule. The metamorphosis consists in a loss of the epithelial covering, due to friction, the presence of perspiration and irritating secretions. A moist, secreting surface is left, the moist papule, which is commonly termed a condyloma, and is of special clinical importance on account of its frequency, its diagnostic significance, and the fact that its secretion is highly infectious.

Macules and a few pustules are usually present with the papular syphilide.

The Pustular Syphilide.—This usually develops from the papular eruption, in neglected cases and debilitated subjects. The most common time for this eruption is late in the secondary stage. When occurring early, it indicates a severe form of syphilis. The pustules vary in size from a split pea to a twenty-five-cent piece. They may develop on any skin surface, but are usually few in number and more frequently located on the face, the scalp and legs. When pustular lesions heal they leave morbid pigmentations, which gradually fade or leave permanent cicatrices.

The Pigmentary Syphilide.—This is rather a rare manifestation, occurring as a distinct expression of the disease, not being secondary to a papular or pustular eruption. It occurs much oftener in women than in men, and may co-exist with other lesions of the skin or mucous membrane. Its color varies from a light yellow to a deep brown shade. Its most common location is the sides of the neck,

though it may be found on the chest, the flexor surfaces of the limbs, and the forehead. It lasts for several months, never scales, and gradually fades, the skin resuming its natural color. This eruption is little influenced by treatment.

Involvement of the mucous membrane of the mouth and pharynx is one of the most common and constant symptoms of constitutional syphilis. It occurs as one of the earliest secondary manifestations, and may continue to re-occur during the secondary stage. It may appear in the form of an acute erythema, involving the palate, half arches, tonsils and pharynx, closely resembling a catarrhal sore throat. The most common form of involvement of the mucous membrane is the mucous patch, commonly located on the tongue, buccal mucous membrane, half arches and the tonsils. At first the mucous patch appears as a pearly white or grayish white round spot, not elevated. As usually seen, the pellicle of mucous membrane has sloughed off, leaving a shallow, sharply-defined "punch-out" looking ulcer. Together with the mucous patch, there are often erosions and fissures of the tongue. In order to differentiate the mucous patch from ordinary aphthous spots it is often necessary to take into consideration the history of the case, and the presence of other signs of syphilis.

Alopecia frequently occurs in early secondary syphilis. It results from the impaired nutrition of the hair follicle, and occurs as general thinning or bald spots. Usually the scalp, as sides and back of head, and the eyebrows are alone affected. The broken arch being very significant of syphilis.

In conclusion, I should like to emphasize the three most reliable diagnostic points of the primary stage which are:

1. Period of incubation exceeding ten days, the average of which is twenty-one days.

2. The induration of the base of the chancre, which is often cartilaginous in character, and feels like a foreign body under the skin.

3. The indolent and painless swelling of the nearest lymphatic glands.

Streptococcus Sore Throat (Pseudo-Diphtheria).

BY F. E. WAXHAM, M. D.,

Professor of Medicine, Clinical Medicine, Laryngology and Rhinology in the University of Colorado.
Denver, Colo.

As its name implies, streptococcus sore throat (pseudo-diphtheria) is an infection by the streptococcus. It is a dangerous condition and should be distinguished from diphtheria or folliculitis at the earliest possible moment. This differentiation is conclusive only after bacteriological investigation. Clinical symptoms differ somewhat from those of true diphtheria, but even these symptoms are not absolutely reliable in making a diagnosis.

In this condition the pharynx is more affected than the larynx. The disease is ushered in by the usual symptoms of a general infection. Chill is usually the first symptom, followed by swelling of the tonsils, high fever, rapid pulse and aching of the limbs. The membrane resembles that of diphtheria to a certain degree, but is not so extensive as in the latter disease; the pain in the surrounding tissues is more intense and the inflammation greater than in diphtheria. Unlike folliculitis of the tonsils, there is ulceration and an exudate occupying the site.

In the streptococcus infection we rarely get the fluctuation which occurs so frequently in parenchymatous tonsils. Diphtheric antitoxin has little, if any, effect in arresting the disease, although the streptococcic serum, when given in full doses and often repeated for a number of days, will frequently relieve the condition or retard its progress.

The disease usually runs a course of from ten days to weeks, but death not infrequently occurs inside of a week, and many of these cases prove fatal in spite of all treatment.

The most dangerous complication is acute nephritis. The kidneys are almost invariably involved in this disease, and there must be suitable treatment for this condition.

Fortunately, the disease is a rare one. I have seen quite a number of cases, two of which proved fatal. One case, which occurred two or three months ago, made a slow but complete recovery after we had practically abandoned all hope. The serum treatment in this case proved ineffective, there was acute nephritis throughout the course. Bacteriological examination confirmed our diagnosis, and microscopical investigation revealed the streptococcus instead of the Klebs-Loeffler bacillus.

Treatment.—Treatment is supportive. Nourishment and stimulation are most important factors in the treatment of this disease. The anti-streptococcus serum is indicated. Strychnia and nitro-glycerine are aids in treatment. As stated, the kidneys usually demand attention throughout the disease.

Prognosis is unfavorable; particularly so if the disease is not recognized early and treated accordingly. Our main hope lies in the early diagnosis, which can only be satisfactorily made by means of the bacteriological investigation. The prompt use of anti-streptococci serum in the earliest stages, with suitable nourishment and stimulation, and proper care of the kidney complication, will often tide the patient through this dangerous condition.

Concerning the Prevention of Typhoid in Military Practice.

BY S. P. KRAMER, M. D.,

Late Major and Surgeon U. S. A.; Lecturer on the Principles of Surgery, University of Cincinnati. Cincinnati, Ohio.

I shall, no doubt, be regarded as heretical by many of my friends when I mildly suggest that the cause for our failure to prevent typhoid fever during the Spanish-American war, may be found in our lack of definite knowledge concerning the method of spreading. My belief in this respect is based on the following history:

Previous to 1898 the profession was practically united in the view that the water supply was the principal medium through which typhoid fever was spread. In fact, we heard nothing else.

In 1898, we took the Seventh Army Corps to Jacksonville, Fla. We extended the water mains of the town (supplying artesian water) to the camp, so that every company had hydrant service, and the only water consumed was the same as that supplied to the 25,000 inhabitants of Jacksonville, a water positively free from contamination. The city itself was practically free of typhoid fever, while the Seventh Army Corps had a very large percentage of morbidity from that disease. It was then that we became convinced that typhoid was not necessarily a water-borne disease, and it was then that the fly theory became prominent as a substitute.

In the report of the chief surgeon of Admiral Togo's fleet, as presented by our distinguished colleague, Admiral Zuzuki, we are informed that in a command of twenty-five thousand men, consuming sterile, distilled water, with a sewage disposal that was ideal (in that it went into the sea as soon as voided), protected by the exigences of war from outside contamination, there was a morbidity from typhoid of nearly one per cent; a morbidity which, had it occurred in the city of Detroit, would have yielded three thousand five hundred cases, and would certainly have been considered an alarming epidemic.

If the Japanese army in Manchuria had no typhoid epidemic, and the Russian army none, and it appears from the report of Colonel Havard that such was the case, they were fortunate. But is it fair to assume that the absence of typhoid in the Japanese army was due to the excellence of their sanitary organization, or that the same absence in the Russian army was due to the poor sanitary organization, and that the presence of typhoid in the American army during the Spanish-American army should be laid entirely at the door of the line officer who failed to heed the suggestion of the medical corps? Such an assumption is scarcely logical, and I think it would be wiser for us to take the position that our knowledge on the subject is as yet inexact. If the armies in Manchuria had no typhoid, it behooves us by patient and scientific inquiry to determine why, rather than to

indulge in polemics at the expense of the reputation of our own army.

We meet with no opposition from the officer of the line in our management of variola or diphtheria. Here we have accurate knowledge, so that all men can see: there is no question; our recommendations are obeyed to the letter.

Much has, likewise, been said and written in the way of invidious comparison regarding the care of the sick in the Japanese and American armies. Let us look, for a moment, on this side of the subject.

During the Spanish-American war we had a mortality from typhoid of about seven per cent. Where will you find anything better than this? Certainly not in the Japanese army, and scarcely in the best civil hospitals of any nation. Now, if a low mortality from typhoid fever means anything at all, it means a high degree of efficiency in the care of the sick, since it is that and nothing else which keeps the mortality down.

Nor has our army medical administration escaped criticism; much of it, I may say most of it, undeserved. As an instance of our lack of efficient administration, Major Seaman quotes the fact that when he went to Porto Rico, he begged for a microscope and could not get one. I want to say that when I went to Cuba, in the service of the army, I did not beg for a microscope, I took one along. I refer to this only for the reason that I desire to emphasize the fact that no amount of administrative care will remedy a lack of individual effort.

Just at present the medical profession is suffering from a wave of organization fever. We preach that all the ills that threaten mankind will be prevented by a proper organization of the medical profession, and its proper recognition of the laymen. But I think it will be found, in the long run, that preventable diseases will not be prevented by polemics, but by a careful and conscientious inquiry into their causes and methods of propagation.

[Written for the MEDICAL BRIEF.]

The Value of the X-Ray in the Early Diagnosis of Osteomyelitis.

BY SAMUEL B. CHILDS, A. B., M. D.,

Professor of Anatomy Denver and Gross College of Medicine; Radiologist to St. Luke's, Mercy and City and County Hospitals.
Denver, Colo.

I have been prompted to bring this subject before you on account of the comparative frequency of the disease and, furthermore, from the fact that in many cases we are unable to make a diagnosis by the ordinary methods of palpation and inspection; or, if a diagnosis can be made, it is impossible accurately to locate the focus of the disease until extensive destruction of the bone has resulted.

It is an easy matter, generally, to make a diagnosis in an old case of osteomyelitis when extensive proliferation of the bone has taken place, or when one or more sinuses are leading directly into the

FIG. 1. Left Leg. Antero-posterior view, antero-posterior half of right leg. Right leg showing the marked enlargement of the tibia and also of the fibula; enlargement of the tibia and three light spots which were the seat of pus foci.

cavity of the bone, but if we stop to think for a moment how much suffering and loss of time this has entailed upon the patient, and how much time is yet required before recovery is complete, we are forced to admit that nature has made the diagnosis for us, and that the patient has paid very dearly for that diagnosis.

There are two well-recognized forms of osteomyelitis, the acute and the chronic. In the former we have an acute infectious process caused, in the majority of cases, by the staphylococcus pyogenes aureus, and in these cases death not infrequently

results in a few days from pyemia or septicemia. In the milder cases, complete resolution may take place in a few weeks, or destructive changes may occur in the bone, giving rise to one or more localized abscesses in the medullary canal, or ne-

FIG. 2. Lateral view of left knee. Femur, marked roughening of the bone with thickening, three inches above the knee joint, enclosing a diamond shaped area which was the seat of the pus cavity.

crosis of the bone adjacent to the affected medulla. Considerable time may be required for these changes to take place. Occasionally the disease may be, apparently, dormant for a time, only to reappear with renewed vigor in pursuing its destructive course. When an abscess has resulted, there is an accompanying characteristic thickening of the bone near the focus of the disease, and, frequently, there is associated with this process a periostitis, so that in any case there may be coexistent an osteomyelitis, an ostitis, and a periostitis.

Osteomyelitis occurs more frequently in men than in women, and the long bones furnish a favorite locality for its development, especially the femur and tibia.

An injury to a bone may furnish a suitable location for the development of an acute osteomyelitis. It has also been observed, as a sequela of the acute infectious diseases, such as diphtheria, scarlet fever, measles and typhoid fever, as well as acute suppurative diseases of other organs.

In the chronic form, a tubercular, syphilitic or actinomycotic inflammation can produce the disease, in addition to the causes enumerated under the acute form, and under the heading of injuries to a bone I would particularly mention compound fractures.

The form of osteomyelitis that I wish to consider is that in which some comparatively slight destructive change has taken place in the texture of the bone or medulla, which process may be characterized either by one or more spots of local softening of the bone structure, or where there are one or more foci of destruction of the bone, accompanied by the formation of a grumous serum or pus, prior to any extensive thickening of the bone, or possibly, any change which may be palpable.

A few explanatory words of the action of the X-ray in helping us in a diagnosis of these conditions may be permissible at this time.

A skiagram is a shadowgram. The inorganic salts, which are normally present in a bone, which give to the bone its firmness and solidity, offer such an impediment to the passage of the X-ray that a more or less dense shadow is engrafted upon the photographic plate. The denseness of the shadow being proportionate to the volume and intensity of the ray employed. Assuming, then, that the X-ray has had sufficient volume and intensity in any given case, there is depicted upon the sensitized plate the normal grain (so to speak) of the bone, and it is as apparent as the grain in many varieties of wood. Any change from the normal grain of the bone should at once attract our attention, and in these cases where

FIG. 3. Lateral view of the middle of the right; marked roughening and thickening of the bone is presented. White area in the center of the picture shows the site of pus cavity.

there is a loss of the bone structure, with or without the formation of pus, there is at these points a less resistance to the passage of the ray, and, consequently, a darker or thinner shadow on the plate.

It is by means of this principle that the X-ray can demonstrate accurately slight changes from the normal shadows, and it is up to the X-ray operator to interpret these changes correctly, with the added aid of the clinical symptoms in the case. Pain, however, which is generally present, is oftentimes referred to a neighboring joint; while, in reality, the focus of the disease is situated in the shaft of the bone, some distance from the joint, as is well illustrated in three of the cases that I report, so that the location of the disease from the seat of pain is unreliable, and the X-ray findings must be judged independently of this one symptom.

If the disease is shown to be limited to a certain area of the bone, this alone should be explored by the surgeon and

Fig. 4. Antero-posterior view of the lateral end of the right tibia and fibula, showing marked nodular condition of the bone. The light areas indicating pus cavity.

he can finish his work with the reasonable assurance that the rest of the bone is not affected, a satisfaction rendered possible by the aid of the X-ray.

Case 1.—Referred by Dr. George B. Packard. Girl, aged twelve. For the past year had not been feeling well, and had been treated for a considerable part of that time for rheumatism. General condition was poor, had lost flesh, and at the time of examination was complaining of pain, which was chiefly referred to the right knee joint. Some thickening of the femur above this joint was palpable. Diagnosis, osteomyelitis of left femur, with an area of softening two inches above the inferior articular surface. Operation was performed by Dr. Packard, July 12, 1903, and well-marked eburnation on the inner side of the lower end of the femur was found. Having chiseled through this, a small cavity was found, from which about one drachm of pus evacuated. This area of softening was found, as indicated by the skiagram, two inches above the inferior articular surface of the femur.

Case 2.—Referred by Dr. C. A. Powers. (Illustration No. 1.) Male, aged thirty. In the latter part of 1902 patient sustained a compound fracture of both bones of the right leg above the ankle. It was nearly two years before union took place in the bones and the skin openings healed. He has had pain continuously near the seat of fracture since the original injury, is unable to bear the weight of his body upon this leg, on account of the increased pain. He has lost some weight. An ulcer was present at the time of examination on the inner side of the leg, about four inches above the internal malleolus. Skiagram was made November 2, 1905. Diagnosis, osteomyelitis, with an area of softening four and one-half inches above the internal malleolus. Operation performed by Dr. Powers, November 6, 1905, and conditions found as shown by the X-ray.

Case 3.—(See illustration No. 2). Referred by Dr. Leonard Freeman. Male, aged twenty-two. In 1889, patient was hit by a hatchet just above the left knee. Was four years in recovering from this injury. During this time small spiculæ of bone worked out two or three times in this locality, but patient had no further trouble with the leg until about October 1, 1905, when pain developed which was most marked in the left internal condyle and knee joint. No swelling was noticed in this region until about November 1. Some stiffness of the joint was present at that time. Skiagrams were made November 11, 1905. Diagnosis, osteomyelitis of the lower end of the femur, with an area of softening two and one-half inches above the articular end of the internal condyle. Operation was performed by Dr. Freeman, November 15, 1905, and the area of softening was found at the point indicated by the X-ray. A little over a drachm of pus was evacuated from this cavity.

Case 4.—(See illustration No. 3). Referred by Dr. Leonard Freeman. Male, aged forty-four. When patient was eight

years of age was confined in bed for about ten weeks by an abscess in the lower end of the right femur. Abscess finally broke above the condyles and several pieces of bone worked out from either side of the thigh in this locality. This process consumed about three years of time. No

FIG. 4A. Lateral view of the right tibia showing nodular condition of same. Several isolated small white spots show the areas of bone softening.

further trouble was experienced until eight years ago, when he had an attack of so-called rheumatism in the neighborhood of the right knee. Was laid up in bed for four weeks at this time. The symptoms, however, were of about the same character as those complained of at the time of my examination. In July, 1905, was obliged to quit work on account of the pain in his right knee, and has been confined to the house since that date. He has lost much weight, has no appetite and looks anemic and sick. His pains are mostly at night, and are referred, chiefly, to the right knee and hip joints. Tenderness over the middle of the shaft of the femur can be elicited by firm percussion. Patient is unable to bear his weight on his right foot on account of the pain on the inner side of the knee. Skiagrams were made November 26, 1905. Diagnosis, osteomyelitis of the right femur, with an area of softening commencing five and one-half inches above the articular ends of the condyle, and extending for about four inches toward the hip joint. Operation was performed, December 4, by Dr. E. F. Dean, Dr. Freeman having referred the case to me during Dr. Dean's absence from the city. The area of softening was found at the point indicated by the X-ray, and one and one-half ounces of thick, heavy pus were evacuated.

Case 5.—(See illustrations 4 and 4a). Referred by Dr. I. B. Perkins. Male, aged fifty-two. When forty years of age patient fell from a step ladder and sustained an injury of his right leg. Ever since that time has suffered with intermittent pains in that leg, principally at night. Two years after receiving the injury the bone became enlarged, and fourteen months ago a discharging sore appeared upon the leg, which, however, responded to systemic treatment and healed. A history of syphilis of twenty-five years' standing was obtained. The pains in the leg have continued up to the present time. An ulcer was present on the inner side of the tibia about three inches above the internal malleolus, but a probe could not be passed down to the bone. Skiagrams were made November 29, 1905. Diagnosis, ostitis of tibia, with several small areas of softening, commencing three inches above the internal malleolus and extending up the leg for a distance of about

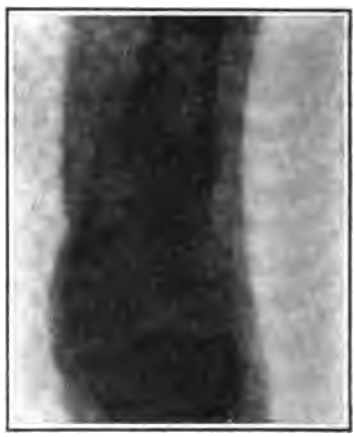

FIG. 5. Antero-posterior view of right femur showing resulting union from compound fracture. The two light areas on either side of the middle line, about three inches above the knee joint show the seat of the two pus cavities that were present.

three and one-half inches. Operation was performed by Dr. Perkins, December 7, 1905, and areas of softening, as indicated by the X-ray, were readily found.

Case 6.—(See illustration No. 5). Referred by Dr. C. A. Powers. Male, aged

forty. In January, 1904, patient sustained a compound fracture of the femur in its lower third. Was operated upon at that time and several fragments were removed. Since then a sinus has persisted above the internal condyle. Since the injury there has always been considerable pain above the knee joint and the inner side of the thigh. The motion of the joint is restricted. Was operated upon in July, 1905, when the sinus and bone cavity were thoroughly curetted. In September, 1905, a similar operation was performed. Skiagrams were made December 12, 1905. Diagnosis, osteomyelitis of the lower end of the right femur, with two areas of softening, one on the inner and the other on the outer side of the femur, each three inches above the articular surfaces of the condyle. Operation was performed De-

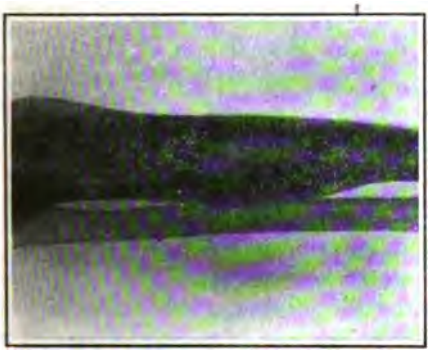

FIG. 6. Lateral view of left tibia and fibula. The middle of the picture shows the marked thickening that was present in the tibia, and the light area indicates the site of the bone softening.

cember 21, 1905, by Dr. Powers, and a softened cavity containing grumous pus, was found on the outer side of the femur, at the point indicated by the X-ray, and a larger cavity was found on the inner side, with which the sinus on the outer side of the thigh communicated, as is shown in the skiagram.

Case 7.—(Referred by Dr. George B. Packard). Girl, aged sixteen. Pain and tenderness had been present over the right trochanter for about four months. Patient had been in bed for six weeks. Motion was not limited at the hip joint. No definite history of an injury. Skiagram was made December 15, 1905. Diagnosis, periostitis, with superficial softening of the great trochanter. Operation was performed December 20, 1905, by Dr. Packard. The periosteum was found very much thickened over the great trochanter, and the lower part of the great trochanter was found covered with an area of purplish granulation, and a small area of superficial softening.

Case 8. (Illustration No. 6.) Referred by Dr. C. K. Fleming. Male, age thirty-one. In September, 1904, patient fell from a bicycle, but was unconscious of any injury to his left tibia, but bruised his left hip, knee and ankle. In January, 1905, detected soreness in the upper part of the left tibia, but had had some rheumatic pains prior to this date, and did not pay much attention to this attack. In January, April, June, August and November, 1905, had periodical attacks of pain in that part of the left tibia, associated with fever and acute inflammation of the left leg, which confined him to bed from two days to two weeks. Skiagrams were made December 18, 1905. Diagnosis, osteomyelitis, with areas of superficial softening six inches below the inner tuberosity of the tibia, associated with a periostitis at these points. Operation was performed by Dr. Fleming, December 22, 1905. Pus was found beneath the periosteum, and the cortex of the bone was diseased, as indicated by the X-ray.

Relationship of Dentistry to Medicine.

BY W. E. GRANT, M. D., D. D. S.,

Professor of Orthodontia and Dean of the Louisville College of Dentistry.
Louisville, Ky.

Probably no branch of general medicine has advanced in the last ten years as rapidly as that of dentistry. This is especially true in regard to the detail of the work undertaken, and the decided advance that has been made along the line of general technique, as well as the special technique of the various important operations. It is true, also, that more strictly scientific work has been brought about within the last few years than at any other period within our professional history.

I take it that there can be no doubt, in the mind of the thorough student, but

that any of the healing arts are but outgrowths of the parent profession of medicine, and recognizing this fact, dentists and other practitioners must work upon the idea of specialists of medicine, no matter what the collateral branches may be.

In addition to the general advance made in dentistry, as a department of medicine, it is also worthy of our notice to consider the advance in the science and art of orthopedic dentistry. It may be considered either from the standpoint of general dentistry, or as a branch almost distinctive within itself, yet dental in its make-up because of the mechanical features and ideas employed, or from a surgical standpoint as surgical procedure is often resorted to for the correction of these abnormal conditions.

To have announced, only a few years ago, that the entire facial contour and physiognomy could be changed without any ill results, either locally or affecting the general system, would have been considered impossible, yet these results are accomplished to-day, and their procedure accepted as a matter of course among the men working in this field.

So much has been found necessary in this department of dental irregularities that the general practitioner of dentistry has felt himself unprepared to meet the demands made upon him, and the work requires much time and constant attention, the busy practitioner finds it impossible to give the necessary time to the work, therefore much encouragement has been given to those who are doing this special work.

It is important that the general practitioner of medicine should realize the possibilities, and that the opportunities are to be had, for the complete restoration and positive correction of practically all the abnormal conditions about the mouth and face. He should also realize that, in many instances, it is important that these cases be referred to the proper specialist early in life, and even before they have come under the observation of the family dentist. Of course, the family dentist is in position to give a great deal of advice regarding the proper procedure.

Irregularities growing out of the presence of adenoid growths and their too long retention, are very common, and in the treatment of these conditions, the dentist associated with the aural and oral surgeon can accomplish great good.

It is not only important that these dental abnormalities be recognized early, but that an active campaign toward their correction and retention in the new permanent position should be carried out.

Much more could be said regarding irregularities in throat conditions, enlarged tonsils, the evils of thumb and lip sucking, all of which come under the observation of the general practitioner, but they will have to be considered at some future time.

Signs and Symptoms of Pregnancy.

BY ROBERT B. ROME, M. D.,

Professor of Gynecology in the College of Homeopathic Medicine and Surgery, University of Minnesota. Minneapolis, Minn.

Considered from a medico-legal standpoint the diagnosis of pregnancy becomes one of deepest interest and utmost importance. Character, social position and legitimacy are at stake, and I can not too strongly emphasize the importance of being thorough in search for every available sign and symptom, and they are almost as many and as varied as the breezes on a changeable April day.

The most marked changes, as one would naturally expect, take place in the organs of generation. Yet there are general modifications or disturbances affecting the whole system, physical, psychical and spiritual.

We find that the initiation of a process of conception within the uterine cavity sets up a process of hypertrophy and hyperplasia of the muscular structures of the uterus, and this in turn gives added capacity to the cavity of that organ. The uterus at term is twelve inches long, nine inches broad, eight inches thick, and weighs about two pounds with a capacity of 400 cubic inches. The characteristic alteration is found in the veins of the uterus. These lose both external and middle coats, so that the intima is in direct contact with the muscular structure. This

is Nature's safeguard, for when the uterus is emptied no resistance from these walls enables the contracting muscular layers of the uterus to close the lumens of the bleeding veins, and in that way prevent hemorrhage.

The nerve supply becomes increased and sensitive. Lymphatics enlarge and become very active, so that septic material is easily absorbed.

Position of the uterus varies in the different periods of gestation. During the first month there is a descent also and anteflexion; following this change is a progressive rise of the organ until about two weeks before term, when there usually occurs what is called the "falling." This primary falling causes frequent micturition, as does this secondary falling. A slight rotation of the uterus on its axis from left to right takes place, due to position of intestines. This is called lateral obliquity of uterus. Increased mobility of the pelvic joints takes place.

Cramps of calves occur from pressure of gravid uterus on several plexus nerves. Varicosities and edema also occur from pressure of pelvic contents.

Blood is also altered, increased in quantity but decreased in quality—increase in white corpuscles and a corresponding decrease in the red corpuscles. Also a marked increase in fibrin takes place. This is another of Nature's precautions. This modification causes the blood to clot rapidly.

An increased amount of urine is secreted. Specific gravity is low, due to the watery condition of urine. No alteration in the amount of urea and solids. Traces of albumen and sugar are frequently observed. The traces of albumin are often due to vesical catarrh. The glycosuria is due to a lactosuria caused by absorption of lactose from the breasts.

Nervous symptoms usually occur. Vertigo, syncope, neuralgia.

Specific Signs and Symptoms.—There are four methods of diagnosis, and all four must be thoroughly practiced in different periods of gestation in order to make a positive diagnosis.

1. Interrogation.
2. Palpation.
3. Inspection.
4. Auscultation.

What may we learn by interrogation? We may learn that were we to depend upon this method alone we could be most magnificently deceived. And this might be voluntary and involuntary on the part of the patient. From questions, however, some facts may be learned in regard to the menstrual function. One or more menstrual periods have been missed. Frequent urination is complained of, also constipation or diarrhea. "Morning sickness," longings or "pica," as it is technically called. Also tingling sensations in the breasts, and enlargement of breasts.

By palpation we can discover indications much more certain. Very early in pregnancy Goodell's sign can be found. By this is meant a softening of the intravaginal portion of the cervix. The sensation imparted to the trained touch in case of pregnancy of two months is best described in Goodell's own words: "The end of the cervix will be as soft and velvety as your lip; if not pregnant as hard as the end of your nose." Of course, this is an arbitrary description, and what would be soft to the touch of one finger would be hard to another. Actual experience alone gives value to this sign.

The progressive growth is another sign we learn by palpation. The tumor of pregnancy, as it is called. This is a presumptive sign only. The antero-posterior flattening of the uterus disappears and the organ becomes globular or pear-shaped very early in pregnancy. The uterus rises progressively, so that at the end of the second month the fundus is on a level with symphysis above. At the end of fourth month fundus is found midway between symphysis and umbilicus. At end of sixth month on the level of umbilicus. End of seventh midway between umbilicus and ensiform cartilage. At end of eighth month on the level of ensiform cartilage, and eight and one-half months it begins to progressively fall until full term. Another valuable sign elicited by palpation is known as Braxton Hicks' sign; it is the rhythmic and painless contractions and relaxations of the uterine walls. It is these intensified that constitute the normal labor pains. They can be detected as early as the fourth month and occur whether the fetus is dead or alive. They are felt by simply grasping

the fundus between the palm of the hand externally. Their frequency varies between five and twenty minutes and lasting about a minute. This sign is presumptive only.

Ballottement is still another sign of great value, but is elicited only in the latter half of pregnancy. It is an absolute and positive sign of pregnancy when found with certainty. To witness it the uterus should be steadied by placing the hands on either side of the abdomen, and an impulse given to one hand, when, in a few moments, a shock is felt on the opposite side. This is called abdominal ballottement.

Cephalic ball: This sign is diagnostic of breech presentation. It is discovered by the swinging movement of fetal head at the fundus of the uterus. Palpation gives us also the vaginal pulse. This sign is found in high arterial tension of the parts and is merely presumptive in value.

Palpation furnishes another most valuable sign, almost positive of pregnancy, Hegar's sign. This sign is elicited in three different ways:

1. Hook down the cervix with a volsellum forceps, then pass the index finger into the rectum and the thumb of same hand into the anterior vaginal fornix. At the same time press the fundus down with the other hand.

2. Place index finger in the posterior vaginal fornix and firm pressure made with either hand just above symphysis.

3. Place finger in anterior vaginal fornix and pass fingers back of the fundus from above between the uterus and sacrum, bringing the lower uterine segment between the fingers of opposing hands. The sensation sought in all these ways is a soft, yielding sensation of that portion of the uterus called the lower uterine segment. This sign is of great value, but not positive. Sometimes it can not be found, and some cases require anesthesia. It can be recognized as early as the second and fifth months.

Another sign found by palpation is that of "uterine fluctuation, or Rosch's sign." Only a presumptive sign, caused by the liquor amnii, elicited by placing one finger in the vagina up against the lower uterine segment and the other hand on the fundus, giving the top to hand, and the fundus transmits it to vaginal finger.

The last sign found in palpation is the detection of the fetal movements—this is, of course, a positive sign of pregnancy. Fetal movements are not to be confounded with quickening. The latter is the initial movement, all subsequent are called fetal movements.

Inspection.—Is the third method and by it we discover important signs.

1. That of abdominal enlargement, not diagnostic, and yet always present in pregnancy in latter months. We notice the striæ caused by rupture of adipose subcutaneous, not always present, can be largely prevented by the inunction of oil when the walls first begin to stretch.

The umbilicus, at the sixth month, begins to protrude and continues to do so until the latter two weeks of pregnancy and then a slight retraction occurs.

Pigmentation of the skin is especially marked upon the abdomen in the form of a dark line, called *linea nigra*, which in the non-pregnant state, was called the *linea alba* or white line.

Jacquemin's sign is an early and valuable one, though not positive. It consists of a bluish and purple discoloration of the vaginal and vulvar mucous membrane. especially intense about the urethral orifice.

Chloasmata, liver blotches, especially found on the face of pregnant women.

Pigmentation of the mammæ. This is manifested in two ways—as the primary areola. This is very marked in brunettes, less so in blondes. Secondary areola, in latter half of pregnancy, developing outside the primary enlargement of the tubercles of Montgomery, are a strong presumptive sign of pregnancy.

The fetal movement can sometimes be seen, and then we have a positive sign. By the method, auscultation, we detect one absolute and positive symptom of pregnancy, namely, the fetal heart sound. The great drawback to this symptom, and we may say to all positive signs, they are certain only in the latter months of gestation, when so many of the presumptive signs are present that it is scarcely necessary to have positive ones. This sign is called Mayor's, since it was first pointed out by Mayor, in 1818.

Positive Signs and Symptoms.—1. Mayor's sign, the fetal heart sound. The pulse of the mother should be taken at the same time, so as not to mistake the pulsations of the abdominal aorta for the fetal heart sound. This sign or symptom has been detected as early as the fifth month.

2. Fetal movements, when ascertained, are also positive signs, but care must be used not to mistake the peristaltic movement of the bowels, or the sudden contractions of the abdominal muscles, for these movements.

3. Abdominal ballottement.

These three are positive of pregnancy.

It will be convenient to divide gestation into three periods of three months each, and ascertain what sign can be expected in these three respective periods.

1. Two signs and symptoms—menstrual suppression and morning sickness. You may look for the "four soft signs," so called, Goodell's, Hegar's, soft uterine body, and soft and enlarged mammæ with dark areola.

2. Together with the foregoing, you will find Jacquemin's sign, Braxton Hicks' sign, ballottement and quickening.

3. All the foregoing still more marked. Fetal movements and Mayor's sign.

[Written for the MEDICAL BRIEF.]

Cerebellum.

BY SILAS HUBBARD, M. D.,
East Aurora, N. Y.

Various have been the views of different physiologists as regards the functions of the cerebellum. One author suggested that it co-ordinated muscular action; another said it presides over nutrition and perfection of the physical frame. Dr. Gall said it was the organ of amativeness. Dr. Kirk, of Mississippi (MEDICAL BRIEF, Vol. XXXIV., page 661), says it is the organ of vitality. I suppose he ought to call it vitativeness. His method of measurement of the organ is not as good as Dr. Gall's, viz., from the opening of the ears to the occipital protuberance.

There is a glimmering of truth in all these different statements of physiologists. The statement that it presides over the co-ordination of muscular action was plausible to the author, because when diseased or wounded it produced ataxia, and a person with small cerebellum is more liable to chorea, ataxia, and eclampsia.

Then I will say for the physiologist who says it presides over nutrition and the perfection of the physical frame, that where the individual has it large, he has a large neck and a stout, muscular build, and this is about all that seemingly favors Dr. Kirk's theory; but they do not live any longer than people with moderate or average cerebellums. Women have smaller cerebellums than men, yet the average of their lives are longer than that of men. The bull and stallion have larger cerebellums, respectively, than the ox, gelding, cow, and mare, yet their lives are no longer.

Now, as regards Dr. Gall's theory that it is the organ of amativeness, I would say that the adult who possesses it large in his day and generation has a large neck, stout, muscular frame, and much animal force and, of course, *ceteris paribus*, could endure greater sexual excesses than one with a moderate cerebellum and a consequent slender constitution.

Dr. Gall, the professed discoverer of amativeness, had the cerebellum large, although he died at seventy years of age, while I know many octogenarians still living who have the cerebellum moderate or average.

The large cerebellum is an effect of vitality and not a cause. In a family of children the older ones generally have larger cerebellums and are larger and stronger physically than the younger ones, because the young parents have more vitality than the old parents. For the same reasons the young parents produce more children with supernumerary teeth, fingers and toes, etc., than old parents.

The cerebellum is not the organ of vitativeness, or love of life. If there is such an organ, it is in convolutions immediately above the opening of the ears, causing breadth through that region. The feline species, especially, have it large; while the herbivora have it moderate, while the carnivora, in general, have it large, and among mankind those who make the best fight for physical life have it large.

[Written for the MEDICAL BRIEF.]

Leprosy.

BY FREDERICK H. DILLINGHAM, M. D.,

Adjunct Professor of Dermatology New York Polyclinic Medical School and Hospital; Dermatologist St. Francis' and St. Joseph's Hospitals; Formerly Assistant Sanitary Superintendent of the Department of Health, City of New York, Etc. New York City.

Leprosy is a chronic infectious disease, caused by the bacillus lepræ, which was discovered by Hansen in 1874. There are two forms: the tubercular, characterized by the presence of tubercular nodules in the skin; and the anesthetic, where the changes take place in the nerves. Besides, we have a combination of the two.

The tubercular type is the most severe. The period of incubation may last months or years. The patient then becomes depressed, complains of weakness, diarrhea, sweating and other definite symptoms, which are followed by a chill and intermittent fever. Temperature may reach 104° F.; pulse is rapid and weak and there are pains in the extremities. After these symptoms have lasted some time there is edema of the eyelids, ears and face or limbs, followed by erythematous lesions, which are elevated, sharply limited, hyperesthetic, and may be one to six inches in diameter. Sometimes these patches develop without premonitory symptoms. They may persist, showing marked infiltration, or disappear only to reappear with febrile symptoms. Later, brownish papules appear on the inside of these lesions; these may enlarge to the size of a hen's egg. The hyperesthesia subsides and is replaced by diminished sensibility or anesthesia. The mucous membranes become involved. The nodules and infiltrated patches either persist indefinitely, or undergo absorption, leaving an atrophy, or break down, forming ulcers, which are shallow or indolent, with a viscid discharge.

The ulceration may affect various joints, especially the fingers and toes, causing necrosis and loss of the bones. The glands of the neck, groin and axilla become enlarged and often break down. The hair, with the exception of that of the scalp, falls out. When the disease is well developed, there is great deformity and thickening of the skin, giving the face a characteristic appearance. Exacerbations occur, and each time new lesions appear.

The anesthetic form depends on a peripheral neuritis, due to the presence of the bacilli in the nerve fibers, and is sometimes confined to the hands and feet. It is the least contagious, mildest and slowest in its course. The period of incubation may extend over years, and the invasion is, usually, slow, and not as marked as in the tubercular form. There is a feeling of malaise, with vertigo, headache, itching and burning sensations. Fever is absent or slight, and there are areas of hyperesthesia, or numbness, with sharp, lancinating pains. Sometimes pruritus is the only symptom noticed before the appearance of the eruption. Bullæ may form over the peripheral nerves, last only a day or two, and then as quickly disappear, or ulcerate, leaving atrophy of the skin. Red or brownish nodules, the size of a pea or larger, usually appear and increase in size. At first, as a rule, they are hyperesthetic, but when they disappear they leave an anesthetic area. The skin becomes yellowish or brownish in color, scaly, dry, with destruction of the sweat and sebaceous glands. The mucous membranes become gradually involved, and there is atrophy of the subcutaneous tissue, muscles, hair and nails, and the fingers and toes are liable to contracture and necrosis. There is an enlargement of the ulnar and other nerves. Paralysis is a late symptom. Ulceration is common, but less extensive than in the tubercular form.

The mixed is the least common form, and usually begins as the anesthetic; fever and tubercular nodules developing after a few months.

One great difficulty in determining the etiology is the fact that the disease may not show itself for years after the exposure. It is claimed, by some, that eating fish is a cause of the disease, but we find many cases of leprosy among people who never eat fish. Until lately it was considered that it could be acquired through heredity, but this can be denied, as no case of congenital leprosy has ever been observed, and children of leprous parents do not have the disease if removed to other surroundings. Although

there are some who doubt it, most authorities believe that it spreads by contagion, and climatic predisposition and manner of living have a decided influence. It is only slightly contagious, and in countries where leprosy is prevalent few who have proper food or live under proper sanitary conditions, contract the disease.

Although there have been cases of leprosy in New York City for years and no attempt made to quarantine them, not a single case has originated here, and there is no danger of contracting the disease in New York City; the same, however, can not be said of some parts of the South. Many believe it is only communicated after contact, while others believe there is an intermediary host, as in malaria and yellow fever. In tropical countries, where they go barefooted, a large number have the first lesions on the feet, which would seem as though the infection had taken place through an abrasion of the skin. Culture slides, placed near lepers while they are talking, usually show a number of bacilli. Usually the mucous membrane of the mouth and nose, as well as the secretions from the ulcers, may be the means of infection.

Attempts at inoculation failed until Arning succeeded with a criminal, but the proof is not conclusive, as several members of his family were lepers. At Pasteur's Institute, in Paris, they have lately found the bacilli in the spleen, liver and kidneys of guinea pigs, eight months after injecting the bacilli from a tubercular nodule under the skin, and also in the abdominal cavity.

Few physicians have an opportunity of studying leprosy, and an error in diagnosis is liable to give rise to much suffering. The diagnosis, as a rule, should give no difficulty when the disease is developed, but in the atypical forms, and when it develops insidiously, no disease is more difficult of recognition. The prodromal symptoms possess little diagnostic value, and may be mistaken for malaria, but examination of the blood would exclude that. Syphilis is, perhaps, most often confounded with the disease. In syphilis lesions are smaller, more regular in size, and appearing in locations where they are rarely seen in leprosy, and run a more rapid course. In leprosy, we have the characteristic appearance of the face, and deformity of the hands and feet, besides the areas of anesthesia. In lupus vulgaris there are no prodromal symptoms, the disease is limited to a small region, usually the face, and spreads slowly. There is no infiltration, the lesions being softer than the normal skin. In erythema multiforme, there is an absence of areas of hyperesthesia or anesthesia, and febrile symptoms are absent or slight. The lesions, as a rule, are smaller, and leaving the skin in color with, perhaps, a slight pigmentation.

Morphea has no constitutional symptoms, and a patch is normal in sensibility. Vitiligo is simply the loss of pigmentation, besides there is hyperesthesia, anesthesia, or constitutional symptoms in leprosy.

The early stage of the anesthetic form might be mistaken for other diseases of the nervous system, but the presence of patches of anesthesia is of great diagnostic value, together with the enlargement of the ulnar and other nerves. In doubtful cases, examination should be made for the bacilli, but often this does not give conclusive proof, and we often fail to find them in the anesthetic form.

The prognosis is very unfavorable, although the patient may live for years. The disease is worse in the tubercular form. We sometimes see mild, abortive cases, and, in a few instances of the anesthetic type, the disease has died out, leaving only evidence of its changes in the nerves. The process may be very gradual but suddenly an exacerbation occurs and the disease progresses rapidly.

Treatment.—Treatment, as a rule, has not been very satisfactory, but, under improved hygiene, we are able to retard the progress of the disease, and we meet with good results in a few cases. The patient should be sent to a non-leprous country, and the secretions disinfected. The greatest attention should be paid to the general health, especially as to food, regular exercise, bathing, etc. A great many drugs have been tried, but few have stood the test, probably chaulmoogra oil, gurjun oil, used externally and internally, have given the best results. Chaulmoogra oil is nauseating and may be given in milk, but better, perhaps, in

capsules or an emulsion, commencing with three minims three times a day and gradually increasing to twenty. In some cases gynocardate of magnesia or sodium agrees better with the stomach, commencing with one-half grain three times daily, and increasing to three grains. Gurjun oil should be given in an emulsion of powdered acacia and water, five minims three times daily, and gradually increasing the dose. Locally, friction with oil or an ointment will produce temporary improvement, and one of the oils should be well rubbed in about two hours a day. Unna advocates ammonium sulpho ichthyolate internally, and, locally, this prescription: Salicylic acid, ten grains; ammonium sulpho ichthyolate and chrysarobin, each twenty-five grains; vaseline, one ounce. Strychnine has been highly recommended, and has given good results, especially in the anesthetic form. A number of cases have been reported benefited by injecting hypodermically, once a week, one-quarter grain of bichloride of mercury, dissolved in twenty minims of water. Tuberculine has been used, but is dangerous, as it sets the bacilli free, instead of destroying them. A serum obtained from the horse has been tried with poor success. The ulcers should be treated by general antiseptic principles.

148 West Eighty-Fifth Street.

[Written for the MEDICAL BRIEF.]

Some Suggestions on Amendment of the Law Regulating State Boards of Health.

BY W. F. MORROW, M. D.,

Professor of Principles and Practice of Surgery in the University Medical College.
Kansas City, Mo.

Having been a member of the State Board of Health for over four years just past, and having had a good opportunity to observe the workings of said Board, I feel that it would not be amiss at this time to make some suggestion with regard to amendments to the law now in force, regulating the practice of medicine in this State.

My first suggestion is, that the State Board of Health be entirely freed from politics.

Watching the operations of other States along this line, and noting the success which attends their work, I would suggest that in the selection of this Board by the Governor, that he require the medical schools of this State, regular, homeopathic and eclectic, to furnish a list of names of men suitable for such positions on the Board of Health, in order that medical men of special fitness and qualifications be selected for the respective positions on the Board.

The State Board of Health, as a licensing body, is of vast importance to the people of the State and its usefulness is now beginning to be appreciated by the commonwealth.

It is a very important thing that a Board be selected which is especially fitted and prepared to judge of the qualifications of physicians to practice medicine in the State of Missouri. No one outside of the medical profession can fully appreciate the great amount of injury and embarrassment which attend the careless work of an incompetent Board of Health.

I refer to Board of Health because in this State the Board of Health performs a double function, that of licensing physicians to practice medicine, and that of caring for and protecting the people from the invasion of contagious and infectious diseases.

This double function which is in no way kindred, should, in my judgment, be separated, and I would suggest along this line that there be established in the State of Missouri a State Board of Health whose duty it would be to care for the people of the State relative to public sanitation, etc., while the duties of the Examining Board would be strictly confined to the examining and licensing of physicians to practice medicine in this State. This is quite sufficient for any Board if the work is done as it should be.

With regard to the personnel of the Board of Health, I wish to state that during the last legislative assembly, that body prepared two bills which were introduced in the House, creating two separate Boards, of five members each, to be called the State Board of Health and the State Examining and Licensing Board, respectively. In the committee-room these bills were discussed seriatim.

One physician, prominent in the State, was present, and when the question came up as to the men who should be placed upon this Board, he publicly declared that no physician should be placed upon this Board who was a teacher in any medical college in this State. My reply to him was that if he would reverse it it would be nearer correct. However, the committee accepted his suggestion and this section of the bill was so amended.

I take the position that a physician, unless a teacher of medicine, unless experienced in conducting examinations, unless thoroughly familiar with the principles of medicine and surgery, is hardly competent to conduct an examination along proper lines. Of course, I do not suggest, nor did I then, that the Board should be entirely composed of teachers in medical colleges, but I do, and did then, take position that the Board should be largely represented by this class of physicians.

Another suggestion which, I think, is of vital importance, unfamiliar to the ordinary doctor and layman, viz.: that the Secretary of the Board of Health should not be a member of the Board, for the reason that it is unusual to have on the Board a doctor who will make a good secretary. The duty of a secretary is to attend to the executive work of the Board. I would suggest, therefore, that the secretary be selected with a great deal of care and caution. Let him be a man who has had considerable clerical experience, one who is thoroughly adapted to this sort of work, and who can devote his entire time to it. It has been the rule and custom in this State since 1884 for the secretary to be selected from the Board, "according to the law," and the documents and records and paraphernalia of the secretary's office are hauled and carried around over the State and located in the various doctors' offices who are elected to fill this position.

Now, to do good and effective work, this office should be located at Jefferson City, the State capital, where these records can be carefully filed, and where there will be a permanent home for the secretary and the records. I know that when I received these secretarial records a little over four years ago, I received few records that were of any importance or of any assistance to me as secretary elected by the Board. The result was that it took at least a year for me to familiarize myself with the needs and requirements of the office, and to make records that would be of service. No physician could possibly be selected who could undertake to do this work satisfactorily under less than one year's study. There are many questions, legal and otherwise, which arise for his decision; there are many blank records that he must properly fill out and prepare. For this reason a secretary should be selected from without the Board. This would enable him to continue with the Board, and with successive Boards, in spite of political changes, and bring the work up to a high standard, with much benefit to the people of the State.

The changing of the personnel of the Board of Health with each incoming administration has a tendency to prevent that necessary development and advancement which is important to the people of this State. For that reason I make this suggestion, based upon four and one-half years' observation as secretary of this Board.

[Written for the MEDICAL BRIEF.]

Diagnosis of Appendicitis with Differential Diagnosis.

BY WM. R. WELCH, M. D.,

Professor of Gynecology and Obstetrics in the Denver Homeopathic Medical College.
Denver, Colo.

The most constant and characteristic symptoms of appendicitis are sudden pain in the epigastrium, vomiting, elevation of temperature, rapid pulse, moderate bloating and pronounced muscular tension over the right side of the abdomen.

Under the consideration of the former symptoms being conclusive, we must remember there is found an occasional individual variation. The epigastric is reflex only; the real seat of the lesion can be ascertained only upon manual examination of the abdomen.

In the usual case the point of greatest sensitiveness can be located slightly be-

low a line drawn from the navel to the anterior superior iliac spine, and somewhat nearer the iliac spine than the navel; but, remembering that we have individual variations, we sometimes find the greatest sensitiveness, or seat of pain, decidedly below the point above mentioned, and near a line of the pelvic brim. This leads to confusion, especially in the case of women where there is a suspicion of uterine trouble.

In appendicitis pain arising from pressure due to sensitiveness is more marked by pressure over the abdomen than through the pelvis, while in ovarian and tubal trouble the pain is greater from pelvic pressure. Vomiting is nearly always present in some stage of appendicitis, usually in the earlier stage, and is beneficial in the early stage. Persistent vomiting in the later stages is a dangerous symptom, denoting intestinal obstruction.

Temperature and pulse are in general misleading, but in the beginning both rise nearly or to the hundred mark, and may go much higher; later, and in the face of most fatal conditions, the pulse often falls below eighty, which misleads some in making diagnosis. Temperature in fatal conditions often falls low, or is aimless, with a flickering course.

In serious conditions the facial marks of distress are pronounced.

Constipation is usually present, but not a guiding symptom. In the beginning of the attack there are often a few liquid passages.

Pain and vomiting may be said to be the most prominent diagnostic symptoms, and because of this, the conditions most commonly mistaken for appendicitis are gallstones, renal colic, renal calculi, typhlitis, typhoid fever, biliary calculus, etc., etc.

In gallstones the most prominent symptoms are contraction and enlargement of the gall bladder, colic, rise of temperature, clay-colored stools, possibly presence of tumor in region of gall bladder; tenderness over tumor, and nearly whole body; nausea, vomiting, jaundice, indigestion. Excruciating pain in the right hypochondriac and epigastrium, radiating down to the navel, back to the spine, upward to the chest, and even to the shoulder blade. The slightest touch increases the pain.

In renal colic the passage of renal calculus is attended with the most excruciating pain, the pain passing along the ureter, with usually retraction of the testicle on the corresponding side.

In renal calculi pain is usually sharp; it may be constant or spasmodic, and is usually referred to the location of the impaction; the pain often radiates down the thighs and legs.

In typhlitis there is extreme swelling in the right ileo-caecal region. The swelling itself is movable, and its growth is rapid. Pain commences suddenly, is short, lancinating in character, is increased on motion. There is obstinate constipation, which may be followed by intermittent diarrhea. Vomiting is usually violent, and greatest at the height of the disease. Difficulty in urination, numbness of the right leg, sometimes drawing up of the testicle. Fever is more or less violent.

In typhoid fever the attack comes on slowly for several days, usually ushered in with more or less violent chill, followed by fever. The form of the temperature is diagnostic of typhoid fever. Great weakness and prostration, severe headache, dizziness, ringing in ears, sleeplessness, more or less delirium, great thirst, appetite poor, bowels constipated in earlier stages of fever, followed by diarrhea. Often bleeding from the nose.

I would advise you not to lose sight of the fact that a diagnosis of appendicitis is much more difficult in some cases; it is more difficult to accurately diagnose the disease in the female than in the male, for instance. In the former the symptoms may resemble those of appendicitis, but be really due to an inflammatory condition of the uterine appendages, or a co-existing inflammation; the appendix may be imbedded in the inflammatory exudate, and thereby distorted so as to cause error in diagnosis, if the proper landmarks are not considered.

One symptom of great diagnostic value in appendicitis, or a differentiating point, is the degree of muscular tension found in the region of the right rectus muscle.

being absent or of slight degree in pelvic disease.

The migratory habit of the tip of the appendix should be remembered, and thus not mislead in diagnosis. The base of the appendix, however, occupies a well fixed position, and if the characteristic inflammatory pain is located above a line drawn from one anterior iliac spine to the other, it is almost certain to be a case of appendicitis.

[Written for the MEDICAL BRIEF.]

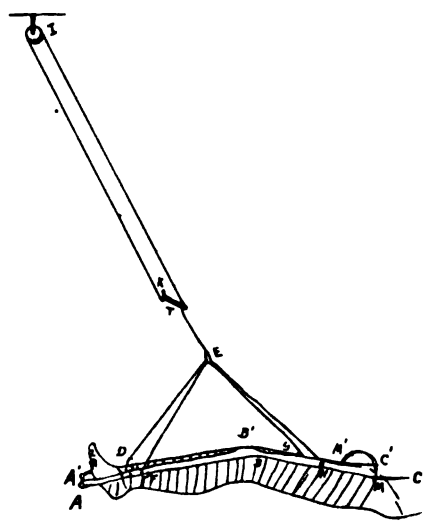
A Plea For a More Extended Use of Hodgen's Suspension Splint.

BY HORACE G. HARVEY, A. B., M. D.,

Professor of Principles of Surgery in the Denver and Gross Medical College.
Denver, Colo.

Hodgen's suspension splint for treatment of fractures of the femur not being in such general use as its merits warrant, and knowing that the majority of physicians are not familiar with its method of application and the advantages claimed for it, I deem that it is not out of place to call attention to its advantages and give in detail a description of its construction and application. Various works on fractures mention the splint, and some give cuts of it, but do not give in detail the method of application.

The splint is made of a single piece of No. 2 wire, bent as shown in diagram. A A^1 is four inches and rests below the sole of the foot. The angle at B B^1 is just enough to give sufficient flexion of the knee for comfort. A^1B^1 and A B are each twenty-two inches. B^1 C^1 and BC each twenty inches, with a slight upward curve near C^1 so that the wire clears the pubes. MM^1 is a bow of No. 2 wire that may be slid up and down the sides of the splint, its purpose being to keep the distance between C and C^1 such as will permit the upper part of the thigh to rest between them, while the bow itself will clear the thigh anteriorly. D, F, G, H, are hooks fitting the splint fairly snugly but movable. D E G and F E H are cords of pliable small rope of equal length attached by their ends to the hooks just mentioned. The pulley I is fastened to the ceiling at such a point, if the ceiling is from nine to twelve feet high, that a perpendicular from the pulley will fall seven to ten inches distally to the sole of the foot. In children this distance should be somewhat greater. If it is not possible to attach the pulley to the ceiling it can be attached to a frame passing up over the foot of the bedstead. E K is a cord looped at the end E around the cords D E G and F E H. The other end of this cord is passed through a hole in the wooden block T, then over the pulley, and finally through the block T again, as indicated in the diagram. T is a block of wood about two inches wide, one-half inch thick and six inches long, with holes in each end to allow the passage of the

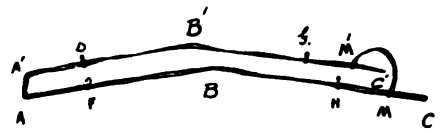


cord, which should go in the direction indicated to give friction for retaining in position. When T is slid down the cord it lifts the splint and the lower extremity clear of the bed.

To apply the splint, place the thigh in an approximately normal position. Apply rubber adhesive plaster, as in Buck's extension. Place the splint about the lower extremity, both the splint and the extremity lying on the bed. The cord passing through the spreader of Buck's extension is then tied to AA^1 short enough so that BB^1 will be at the bend of the knee. Pin an end of a three or four-inch-wide strip of muslin around the side of the splint at the lower end; pass the strip under the heel and pin the other end

to the other side of the splint, so that the heel will rest in a swing. Pin another strip at the bend of the knee and one near the upper end of the splint. Next, slide the block T down the cord and thus raise the thigh from contact with the bed. Strips of muslin are now pinned along the entire length of the limb, from the heel to the gluteal fold, so that it rests in a sort of hammock. Since the upper fragment in fractures high up on the femur assumes a position of flexion and abduction, the lower fragment is brought into line with it by virtue of the elevation in suspension, and the splint should be in a position of abduction to an extent indicated by the upper fragment. The same position is applicable to all fractures of the femur.

The extending force is the weight of the limb exerted through the rubber adhesive attached to the leg and to the splint. The amount of extension is increased by the obliquity of the suspending cord and can be made greater by placing weights on the splint.



In ordinary cases an anesthetic is not necessary. The reducing force furnished by extension continues to act, and a fracture that may not be completely reduced at the time of application of the splint will be in a few hours.

On account of the lack of friction between the limb and the bed the extending force needed is not so great as in other splints. If there is a tendency for the body to slip down, the foot of the bed should be slightly elevated.

A short upper fragment can not be easily controlled by any splint. The lower fragment can be put in line with the upper by the suspension splint. In splints where the limb rests upon the bed, if the trunk is moved the upper fragment moves independently of the lower, thereby favoring non-union and deformity, whereas, in the suspension splint both fragments move together.

With the suspension splint the patient can raise the buttocks to allow the use of the bed-pan, and to facilitate the change of bedding and make the prevention or treatment of bedsores easier; the shoulders may be elevated without disturbing the seat of fracture. The less confined the patient is the better and more comfortable. Because of the greater freedom of movement, the splint is well adapted to the aged.

It is peculiarly serviceable in compound fractures, because the strips of muslin may be removed at any place and leave a free field for dressing. The limb is always ready for inspection; no pressure is produced anywhere; as the muscles atrophy the strips of muslin are easily readjusted.

It is applicable to any fracture of the femur from the neck of the femur down.

The splint can be made by a blacksmith in half an hour. It is easily, quickly and comfortably applied.

The results in my experience are better than with other splints.

Penetrating Injuries of the Eye.

BY HUGH MILLER, M. D.,

Professor of Ophthalmology and Otology in the Western Dental College and Kansas City Veterinary College, Kansas City, Mo.

Sources of external injuries to the eye are legion. For diagnosis and treatment, and especially for prognosis, injuries are classified by various writers and teachers, but such classification or grouping must, necessarily, be an arbitrary one, since, as stated above, the sources of injury are of so great variety. For the student a regional classification may be a useful one, such as injuries to the cornea, eyelid, etc., but for the busy practitioner such a manner of grouping is soon laid aside.

A few facts in the common causes of injury should be sought for, and the information thus gained be made the foundation for diagnosis, prognosis and treatment. Some information may be had from an intelligent patient or companion by word of mouth, but the greater part will, necessarily, require the skill of the attendant, and to be secured

by personal inspection. It is sometimes possible for the patient to state the nature of the injuring body, if it be sharp, a pointed instrument, or a dull one; a clean one, or a foul one; the direction from which it came, and the position of the eye at the time, and many other similar facts which are of great value in gaining a thorough knowledge of the case at hand; but it will be required of the attending physician to verify these statements during the process of inspection. Not that it is necessary to question the veracity of the patient, but one finds too few people who are able to furnish valuable information in such matters, though willing and glad to do so.

A wound made by the point of a knife blade is not, necessarily, a puncture, and it may be a puncture even though those seeking assistance refuse to believe such is the case. For example: A six-year-old boy was brought to my office with this history: The child was seated on the floor, playing with a knife. He suddenly cried out that he had struck his eye. His cries lasted but a moment. His eye appeared perfectly normal. Bedtime having arrived, he was put to bed. Pain did not appear until thirty-six hours after the injury. After carefully examining this eye, I stated to the mother that the point of the knife had penetrated deeply into the eyeball, and had injured the deeper structures and would seriously impair vision permanently, if not wholly destroy it; particularly if it had become infected at the time of the injury, and, from a careful inspection of the wound, I believed that a serious inflammation had started. It was difficult for her to believe that such an injury had occurred, and for this reason I was unable to control the patient as I desired. The facts were present to justify a doubtful prognosis. Though the wound in the cornea showed, at this time, a mere line, the iris was snipped in one point, and plastic material had caused adhesions to the crystalline lens. Of the injury, posteriorly, I was unable to speak, and how deep the point of the knife had passed it was not possible to know. The wound was an infected one, as shown by the progress of the disease, panophthalmitis setting up rapidly. The destruction of vision and the shrinking of the globe followed.

A second case of penetrating wound, which proved fatal to the eye, was that of a young man from Coalesburg, Mo., while hunting with a brother. He was standing near a hedge when a small shot from the gun of his brother, striking hard wood, glanced and passed through the right eye at the upper inner quadrant. It cut a smooth, round hole in the iris. Direction was backward, downward and inward. The shot passed through the orbit, entering the nasal cavity, and was expectorated by the patient. In this case, vision was destroyed, but several years afterward there was but slight change in the appearance of the eyeball. This case, too, I saw but a few times, as both parents and patient could not understand the dangers of the situation.

A third case of penetrating wound I report with quite a different result, which, I believe, was due to the method of treatment. Mr. H., a laborer, while standing some ten feet or more from men cutting heavy iron with hammers and chisels, was struck in the eye with a piece of steel, one inch long and one-quarter inch thick. When he arrived at my office his face and shirt front were covered with blood. The hemorrhage was a copious one. The eyelid was not injured in the least. Pain was not severe at this time. The patient was suffering more from shock and fear of loss of the eye than from actual pain. Upon examination, I found a long, ragged puncture at the inner sclero-corneal junction, sufficient to admit a No. 16 Theobald's lachrymal probe. The only means of ascertaining whether particles of steel yet remained was by the use of magnetic probes. Examination of the vitreous chamber thoroughly with probes, under aseptic conditions, revealed no particles of the missile.

Treatment consisted in bringing the injured parts as near as possible to the normal position. Instillation of one per cent solution of atropin sulphate into the eye every six hours, night and day. The eye was dressed with sterile gauze, giving gentle pressure, and the eyelids kept as quiet as possible. This dressing was not removed until the third day. The patient was kept prone for the first three days,

and in a darkened room, and fed on a liquid diet. The use of atropin was continued, after the first week, three times a day. Healing progressed very favorably from the first. Vision slowly returned. Some months later, I adjusted a glass to the eye. Minus 30/20, while the fellow eye was emmetropic. Had it not been that later this eye became almost emmetropic, we might have thought the eye was originally myopic. At the end of a year the eye was again emmetropic.

How few cases does the oculist, or even the general practitioner, see so promptly or control so perfectly, as this one. Prompt action and close attention are the essentials in all puncture wounds. Be careful not to do too much. Be sure to remove all foreign matter. Put not only the eye at rest, but also the patient. Absolute rest, then follow the procedure of non-interference, unless called to do so by untoward symptoms. Dress and leave alone, save to instill atropin in now and then, as required. If the wound is a central one, atropin should, undoubtedly, be used. Sometimes eserin can be used to a good purpose in punctured wounds near the margin of the cornea, provided the injury does not reach the iris. When near the iris, atropin is the sheet anchor remedy. Cold packs are useful in pain in the early stages, during the first twenty-four hours. Later, they are to be avoided, since either heat or cold produces changed condition of the blood pressure, and sloughing may ensue. Punctured wounds require such perfect, constant attention, that the patient should be placed in a hospital, or attended by a nurse.

Prognosis in all punctured wounds should be given guardedly. A better prognosis can be given if early, skillful attention is given, and strict nursing, and the patient attends strictly to instructions.

In penetrating wounds, with prolapses of the iris, the prolapse may be clipped off, under strict aseptic conditions. Not antiseptic, but aseptic, as the internal structures can not stand antiseptics, even of the mildest kind. It is safer to use pure sterile water only.

To recapitulate, briefly:

1. Learn the nature of the injury and injuring instrument.

2. Ascertain the structures involved in the injury.

3. Endeavor to free the eye of all foreign particles.

4. Restore the parts to their normal positions, as nearly as possible, and at as early a day as possible.

5. Put the eye to rest, absolute rest, and extend this period of rest into days.

6. Follow a plan of non-interference, after the first treatment and dressing, unless indications.

7. Use atropin or eserin, as the case may indicate, instilling it with as little interference with the dressing as possible.

8. Patients with penetrating wounds should give themselves up absolutely to the directions of the physician in charge, and such wounds should have the most careful attention and most perfect technique, and placed under absolute rest. Then, if unfavorable changes appear, it is due to the fact that the injuring instrument was an infection-bearing one, and such a prognosis is unfavorable.

[Written for the MEDICAL BRIEF.]

Diagnosis and Treatment of Intestinal Obstruction.

BY GEO. S. COON, M. D.,

Professor of Surgery and Gynecology in the Southwestern Homeopathic Medical College and Hospital.
Louisville, Ky.

The subject of intestinal obstruction is of equal importance to the surgeon and physician, especially to the latter, as upon his early diagnosis largely depends the outcome of the case.

Obstruction may be either partial or complete, mechanical or dynamic; in the former the treatment is purely surgical, and in the latter purely medical. Clinically, and for very practical reasons, intestinal obstruction is classified as acute and chronic.

Acute obstruction is most frequently above the ileo-cecal valve, while chronic is below it. It should be remembered, however, that chronic obstruction may, at any time, become acute.

Diagnosis of acute obstruction depends upon four cardinal symptoms. Intermit-

tent colicky pain, vomiting, tympanites, and absolute obstipation. Pains are intermittent in character, and are due to the peristaltic action of the intestines. Vomiting is a symptom that is always found, sooner or later, and is more persistent and severer the closer the obstruction is to the stomach, while tympanites is the more marked the further the obstruction is from the stomach. Early in the attack fever is absent, and only appears after gangrene or peritonitis become manifest. Pulse, at first, is slow and full, and becomes weak, thready and rapid only when peritonitis is present. There is no tenderness at the beginning of the attack; in fact, pressure, as a rule, is grateful. There is also entire absence of rigidity of the abdominal muscles, which always assists in differentiation.

The chief causes of intestinal obstruction are volvulus, intussusception, internal hernia, foreign bodies, strictures, bands and adhesions, diverticuli, fecal impaction and, occasionally, tumors. Volvulus is very frequently found at the sigmoid flexure, and is due to elongated mesenteric, with loaded bowel. This is a rapidly fatal form of obstruction, owing to the interference of the blood supply causing rapid gangrene. It is to be diagnosed, in addition to the cardinal symptoms, by the finding of a tumor in the pelvic region, with localized tympanites over the tumor. Intussusception is the most frequent of all the causes, and constitutes about eighty per cent of all cases found in children under six years of age. Its chief symptoms, in addition to those already mentioned, are a bloody mucous discharge, and the finding of a sausage-shaped tumor. The usual location is the ileo-cecal valve. Strictures are more frequently found in advanced age and, usually, at the ileo-cecal valve. In the aged they are usually due to malignant troubles, and in younger individuals to tuberculosis and syphilis. Fecal impaction is most frequently met with in the large intestine, and can be diagnosed by finding tumor, which can be dented on firm pressure, particularly if the patient is under an anesthetic. Internal hernias can usually be diagnosed only after an incision has been made. Foreign bodies are diagnosed from a history of the case, possibly of gall-stones, or the swallowing of some substance by the patient. Bands and adhesions are to be expected following cases of peritonitis or severe operations. Meckel's diverticulum causes a small per cent of cases of intestinal obstruction, and we have no means of determining this before an incision has been made.

Intestinal obstruction must be differentiated from peritonitis, acute indigestion, gall-stones, appendicitis, and various other abdominal troubles. Chronic obstruction is most frequently met with in people of advanced age, middle life. A valuable diagnostic sign is the presence of peristaltic action, which can be perceived through the abdomen in nearly all cases. These patients are, usually, thin, and this permits of an inspection, which is not possible in the case of a fleshy patient; but where present, in either the acute or chronic form, it is nearly pathognomonic, and is never seen in cases of peritonitis.

It is much easier to make a diagnosis of intestinal obstruction than to determine the cause, and, while we should attempt in all cases to determine the location and cause of obstruction, valuable time should not be sacrificed in this, too frequently, vain attempt. A diagnosis of intestinal obstruction having been made, it then becomes more important to relieve the condition than to determine its pathology.

It is agreed, by all surgeons and physicians, that, no matter what the cause of obstruction, food of all kinds, and even liquid, should be withheld from the stomach, as soon as diagnosis is made, since food only irritates an already congested mucous lining, but ferments and increases the gas and distention. Patients should be fed per rectum. Lavage of the stomach has also been found to be of very great benefit, giving marked relief to these patients, as it removes the gas and fermenting material, which is always found in the stomach; in fact, many of these cases obtain such relief from this treatment as to lead to delay in more radical measures. This should never be done. Enemas are resorted to, not only by the physician, but by the laity, and I need only mention them in passing. Cathartics, while nearly always resorted to, are only

to be mentioned to be condemned; they should never be given in cases of mechanical obstruction, because they lash the already overworked bowel into greater contractions, increasing also the distention of the bowel and hastening the fatal process. They are only valuable in cases of dynamic obstruction, which are so frequently found after abdominal operations.

The death rate from operative procedures, in intestinal obstruction, will continue to be high until the profession learn to stop dallying with medicines, and seek early operative interference. Diagnosis of mechanical obstruction having been obtained, no time should be lost in subjecting the patient to operation.

Why Cigarette Smoking Is Injurious.

BY B. W. LINDBERG, C. E., M. D.,

Professor of Chemistry, Toxicology and Urinalysis in the Kansas City Hahnemann Medical College. Kansas City, Mo.

Cigarette smoking has long been known to be injurious to the health, but the reason why cigarettes should be so injurious while cigars and pipes can be indulged in with little or no harm, has been a subject of much thought. The reason lies in the difference of partaking. Cigar and pipe smoke is, as a rule, too strong to be inhaled, while the milder cigarette smoke is generally inhaled, and, as we will see later, the chemical action of the cigarette smoke in the lungs, on the blood, etc., will give us the clue to the havoc wrought.

Tobacco is largely cellulose; of course, as we all know, it contains nicotine, from two to eight per cent. The smoke contains all the products of burning and dry distillation of cellulose (wood), of which we will mention a few: tar, ammonia, carbon dioxide, carbon monoxide, and to these may be added the nicotine and the products of its dry distillation. These are the same, whether the smoke indulged in is by way of the cigar, pipe or cigarette. There is a possibility, however, that the smoke of the cigarette will be richer in carbon mon-oxide because the burning end of the cigarette is longer, and, consequently, the carbon dioxide made in the outer end of the burning cigarette will be reduced to mon-oxide going through the heated carbon before it enters the mouth.

The paper of which the cigarette is made has been accused by many to be the cause of the injurious symptoms that follow cigarette smoking, and it has often been intimated that the manufacturers of cigarette paper put opium in it in order to establish the habit and thereby advance sales. This latter I do not think probable, because opium is a very expensive drug and the paper is very cheap, in fact given away often, and I think we will find the reason of the havoc wrought in another substance.

The products of the decomposition of the paper are about the same as that of tobacco, because the paper is almost pure cellulose. Cigar and pipe smoke is taken into the mouth and from there expelled. The membrane of the mouth and pharynx does not absorb as readily, but still enough of the nicotine is taken up through these membrances to give direct action. Notice the boy who smokes for the first time and see how the nicotine takes effect. Of course, a toleration is soon established, and after awhile greater indulgence is possible. In cigarette smoking, however, there is another factor of great importance; the cigarette smoker inhales the smoke, which means that he takes it deep down into the lungs with the air he breathes and exhales it again. Here we have to do with another kind of tissue—the lung tissue, which membrane is especially made for the osmosis of gases; through this membrane the oxygen of the air is exchanged readily for the carbon dioxide of the blood. This is the ordinary way in which oxyhemoglobin is made in the blood. Oxyhemoglobin, as we know, is rather an unstable compound, readily giving up its oxygen to the various tissues in the body, forming hemoglobin, which comes back to the lungs again for a new supply of oxygen to form oxyhemoglobin.

As mentioned above, we have another gas in fairly large quantities in cigarette smoke. I have reference to carbon monoxide. This forms also a combination with hemoglobin; thus combined, carbon-monoxide-hemoglobin is a very stable compound, and as a consequence the hemo-

globin is lost to the blood. For every molecule of carbon monoxide taken into the blood through the lung, a molecule of hemoglobin is lost. This hemoglobin, as you know, is the most important element in the blood, and in all probability one of the most difficult to generate. This would explain the bloodlessness that we notice in the cigarette fiend, as well as the effect on the brain; the blood being impoverished in the above manner and the brain starved from the impoverished blood.

There are many who smoke cigarettes without inhaling the smoke, and in those we do not observe the awful effects that are noticeable in the "fiend." We must also remember that we have nicotine in the cigarette smoke as well as in the smoke of the cigar and pipe, and this nicotine being inhaled into the lung is taken up much more readily by the membrane, which is especially made for the purpose of gas absorption. Here we see that a small quantity of tobacco in the cigarette will give the largest quantity of poisonous action.

The condition of the brain cells brought about by the diminished tissue change from the lessened oxygen-carrying capacity of the blood, may be responsible for the inability to differentiate between right and wrong, that we find so frequently in cigarette fiends.

Operation for Desperate Cases.

BY FREDERICK A. DUNSMOOR, M. D.,

Professor of Operative and Clinical Surgery in the Medical Department of the University of Minnesota; Gynecologist to City Hospital; Surgeon to Asbury Hospital, St. Mary's Hospital, Swedish Hospital, N. P. Ry., C. St. P. and O. Ry. and "Soo Line," Etc., Etc. Minneapolis, Minn.

At the close of my clinic last Saturday my attention was called to a patient evidently *in extremis*. There was a history of appendicitis, with apparent recovery the week previous. Patient had gotten up and walked about the house on Sunday. The next Thursday she was again taken ill. On Friday a physician was called, who sent her to the hospital on Friday night. Pulse, one hundred and forty; temperature, 102° F.; collapse; mind perfectly clear, but an evident general peritonitis. Pulse one hundred and fifty to one hundred and sixty, and evidence of tremendous septic infection.

This is exactly the case that no one would touch who was operating for a record, but there is a question if every surgeon who has a reputation established should not, at least, do as he would be done by. It seems to me there is a possibility that some of these cases may be saved. And, in accordance with this belief, a few whiffs of ether were given, an incision made, and over two quarts of pus drained from the general peritoneal cavity, and a constant stream of normal salt solution left irrigating through the wound. Patient put to bed with hot bottles; general cardiac stimulation. Died in the evening of the same day.

Now, I am as firm an advocate for early operations as any one; and for the sake of surgery, declining to operate where there is no possibility of curing or benefiting a patient, but in cases like this it is absolutely certain that the patient must die and very soon. If such a peritonitis was one beginning because of the perforation from a gunshot wound, or from typhoid, or gastric ulcer, no one would hesitate, having in view always the certainty of a fatal termination without an operation. Therefore, it seems to me, from a humanitarian standpoint, the surgeon should always open and drain the abdominal cavity where there is a flicker of a chance that the poison may be washed away, on the same grounds that he would operate upon a moribund case of ectopic gestation, with ruptured sac, in order to control the hemorrhage.

There is, of course, the danger that operative surgery is always harmed by any incision that is followed by a fatal termination, but certainly this is the age when the public is more willing to resort to surgery than at any previous time, and I, therefore, make the plea that the patient in desperate straits may be given the benefit of a logical attempt to save life, even though one be added to the mortality record of an ambitious operator. And while I do not believe in hastening a certain death, I do believe in throwing the rope to a drowning person.

Andrus Building.

[Written for the MEDICAL BRIEF.]

Report of Operation for Enormous Tumor in Child of One Year.

BY WALDO BRIGGS, M. D.,

Dean and Professor of Surgery in the Hospital College of Surgeons.
St. Louis, Mo.

AND L. L. C. LEMOINE, M. D.,

Assistant Surgeon, St. Louis, Mo.

Tumors of the neck are matters of grave concern to the surgeon when malignancy is suspected, or rapid growth occurs, accompanied by an alarming degree of inflammation. This case presents all the clinical features of both conditions. The tumor has recently grown to its present enormous size, and the inflammatory process fully developed.

The patient is one year and eleven months old; the condition is congenital, and was noticed at parturition. Family history good. The tumor, an irregular mass, adherent, and extending anteriorly from the occiput to the point of the jaw, being about two inches in depth at the mastoid process, and attained its greatest dimension at a point over the anterior rim of the sterno-cleido-mastoideus—eight and one-half inches laterally and six and one-half inches in depth. Anterior to this point, a third cyst appeared, marked by a change in color and more nearly approximating the normal skin tint. A complete network of dilated arteries and veins enveloped the surface of the tumor. A pronounced distention of the skin surrounded the containing wall of the tumor, and added to the weight of the mass, causing the ear to be pushed upward, and so that the entrance of the auditory canal was almost occluded.

The initial incision was commenced at a point just under the symphysis, and carried posteriorly to the sterno-mastoid, under the deep cervical fascia, the growth being firmly attached to all the tissues of the right side of the neck, and involved the trachea, common carotid, jugular, pneumogastric, the sterno-cleido-mastoid and the platysma in its folds. The growth filled every chink and crevice in the side of the neck, and careful dissection was necessary to effect its removal. Chloroform was the anesthetic used.

When the tumor was first noticed at the child's birth, only two growths were in evidence, about the size of a pigeon egg, and not believed to have any connection, owing to their wide separation in position. At the age of six months the third and largest tumor made its appearance. With its advent, greatly increased activity became noticeable, and soon caused great discomfort to the patient, manifested by the difficulty in swallowing, and interfering greatly with nourishment and sleep.

The little patient soon showed the detrimental effects of impaired nutrition, and assumed the pasty color of general anemia. Some ten days since, the rapid

growth of the tumor, and the great accumulation of its contents, and the irritation produced by friction against the shoulder, overcame the integrity of the cyst wall, and part of the contents was forced out of the lower end of the central sac. The inflammation following the escape of the fluid made measures for the relief of the condition imperative, and the patient was brought to the Jefferson Hospital for operation.

Upon bimanual palpation, some degree of fluctuation was demonstrated, but was more resistant than entirely fluid contents would warrant, indicating (1) an unusually thick outer wall, and (2) a series of inner cysts within cysts. Aspiration demonstrated the contents of the anterior sac to consist solely of serous and sanguineous fluids, the coagulation of the latter being very slowly accomplished. Aspiration of the middle cyst was not carried deeply, as the wide variance in consistency of the contained tissues required a degree of force that made puncture of some involved vessel sheath more than probable.

The posterior lobe contained serous fluid only, and it was shelled out, taking care to remove the entire wall to prevent any renewal of secretion. The firm, hard bodies were seven in number and almost uniform in size, and cord-shaped in conformation, presenting a capsule covering resembling periosteum in color, and of the consistency of rubber, each nodule having a base of fatty-appearing tissue. Dissection was made as rapidly as was consistent with safety, the wound cleansed by irrigation with hot saline solution. Gauze drainage was introduced into the lower part of the cavity. As the procedure was attended with considerable hemorrhage and collapse was imminent, hypodermoclysis was given. On the day following operation the temperature was 106° F., but dropped to normal on the third day. The child is in good health, and a close return to normal condition and appearance has been the result of operation.

The management of these cases is open to the widest divergence of opinion. Some cysts, even when very large, disappear spontaneously, but this is a very rare occurrence. The proper operation is the incision of the tumor.

Electrolysis may cure the simpler cases, but it always substitutes a fibrous tumor for the one in existence, and as this, in turn, will have to be removed, it will leave a scar as pronounced, and the operation for its removal as dangerous, as if excision had been chosen as the original operative procedure.

Setons should not be used. Puncture and drainage are inefficient, excepting in simple cysts, such as hydroceles of the neck. In these single cysts, puncture and drainage may be tried.

The treatment by the injection of iodine is more uncertain than incision, the object of its use being to set up an inflammation extensive enough to obliterate the cysts and cause them to shrivel up and disappear; indeed, this result sometimes occurs spontaneously.. There is always danger of iodine poisoning or setting up suppuration.

Sublingual cysts may be often removed through an incision into the floor of the mouth carried down to the cyst wall, cyst being carefully dissected from its surroundings by a blunt dissector.

Cervical cysts are removed through an incision anterior to the sterno-mastoid muscle. Usually these cysts are not firmly adherent to surrounding parts, and removal is, consequently, not difficult.

Partial or total excision is preferable, but in patients at a tender age this procedure can be carried out only in limited cases. Partial incision, with careful control of hemorrhage, and stopping short of endangering the child's life by a too prolonged and extensive removal, is sometimes successful.

Jefferson and Gamble Street.

March 31, 1906.

Mr. W. J. Moore, the father of the little patient, writes under date of March 30, 1906, stating:

"Well, the baby is growing; he is fat as a pig; walks all over the house. Everybody is surprised to see him well, deeming his recovery impossible."

This is firm confirmation of the diagnosis made by Dr. Briggs, of branchial cyst, excluding sarcoma, a recurrence of the latter failing to make its appearance by however slight a manifestation, always present when sarcoma exists in connection with cyst development.

L. L. C. LEMOINE, M. D.

I herewith enclose my subscription. I give this with real grace and good will. The BRIEF is up to date and practical. For the past it has guided me safely over many a rocky shoal. God bless and prosper the good old BRIEF.—DAN'L MCDONALD, M. D., Baddeck, N. S., Can.

low a line drawn from the navel to the anterior superior iliac spine, and somewhat nearer the iliac spine than the navel; but, remembering that we have individual variations, we sometimes find the greatest sensitiveness, or seat of pain, decidedly below the point above mentioned, and near a line of the pelvic brim. This leads to confusion, especially in the case of women where there is a suspicion of uterine trouble.

In appendicitis pain arising from pressure due to sensitiveness is more marked by pressure over the abdomen than through the pelvis, while in ovarian and tubal trouble the pain is greater from pelvic pressure. Vomiting is nearly always present in some stage of appendicitis, usually in the earlier stage, and is beneficial in the early stage. Persistent vomiting in the later stages is a dangerous symptom, denoting intestinal obstruction.

Temperature and pulse are in general misleading, but in the beginning both rise nearly or to the hundred mark, and may go much higher; later, and in the face of most fatal conditions, the pulse often falls below eighty, which misleads some in making diagnosis. Temperature in fatal conditions often falls low, or is aimless, with a flickering course.

In serious conditions the facial marks of distress are pronounced.

Constipation is usually present, but not a guiding symptom. In the beginning of the attack there are often a few liquid passages.

Pain and vomiting may be said to be the most prominent diagnostic symptoms, and because of this, the conditions most commonly mistaken for appendicitis are gallstones, renal colic, renal calculi, typhlitis, typhoid fever, biliary calculus, etc., etc.

In gallstones the most prominent symptoms are contraction and enlargement of the gall bladder, colic, rise of temperature, clay-colored stools, possibly presence of tumor in region of gall bladder; tenderness over tumor, and nearly whole body; nausea, vomiting, jaundice, indigestion. Excruciating pain in the right hypochondriac and epigastrium, radiating down to the navel, back to the spine, upward to the chest, and even to the shoulder blade. The slightest touch increases the pain.

In renal colic the passage of renal calculus is attended with the most excruciating pain, the pain passing along the ureter, with usually retraction of the testicle on the corresponding side.

In renal calculi pain is usually sharp; it may be constant or spasmodic, and is usually referred to the location of the impaction; the pain often radiates down the thighs and legs.

In typhlitis there is extreme swelling in the right ileo-caecal region. The swelling itself is movable, and its growth is rapid. Pain commences suddenly, is short, lancinating in character, is increased on motion. There is obstinate constipation, which may be followed by intermittent diarrhea. Vomiting is usually violent, and greatest at the height of the disease. Difficulty in urination, numbness of the right leg, sometimes drawing up of the testicle. Fever is more or less violent.

In typhoid fever the attack comes on slowly for several days, usually ushered in with more or less violent chill, followed by fever. The form of the temperature is diagnostic of typhoid fever. Great weakness and prostration, severe headache, dizziness, ringing in ears, sleeplessness, more or less delirium, great thirst, appetite poor, bowels constipated in earlier stages of fever, followed by diarrhea. Often bleeding from the nose.

I would advise you not to lose sight of the fact that a diagnosis of appendicitis is much more difficult in some cases: it is more difficult to accurately diagnose the disease in the female than in the male, for instance. In the former the symptoms may resemble those of appendicitis, but be really due to an inflammatory condition of the uterine appendages, or a co-existing inflammation; the appendix may be imbedded in the inflammatory exudate, and thereby distorted so as to cause error in diagnosis, if the proper landmarks are not considered.

One symptom of great diagnostic value in appendicitis, or a differentiating point, is the degree of muscular tension found in the region of the right rectus muscle.

being absent or of slight degree in pelvic disease.

The migratory habit of the tip of the appendix should be remembered, and thus not mislead in diagnosis. The base of the appendix, however, occupies a well fixed position, and if the characteristic inflammatory pain is located above a line drawn from one anterior iliac spine to the other, it is almost certain to be a case of appendicitis.

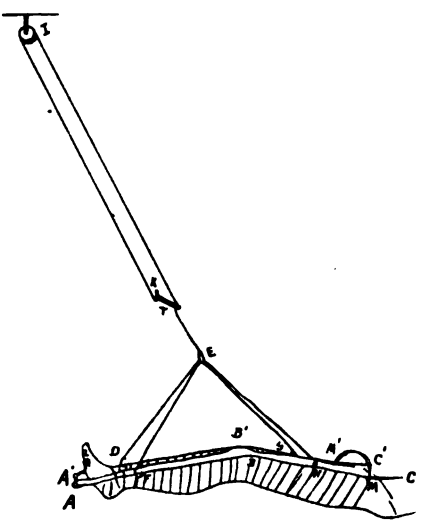
A Plea For a More Extended Use of Hodgen's Suspension Splint.

BY HORACE G. HARVEY, A. B., M. D.,

Professor of Principles of Surgery in the Denver and Gross Medical College.
Denver, Colo.

Hodgen's suspension splint for treatment of fractures of the femur not being in such general use as its merits warrant, and knowing that the majority of physicians are not familiar with its method of application and the advantages claimed for it, I deem that it is not out of place to call attention to its advantages and give in detail a description of its construction and application. Various works on fractures mention the splint, and some give cuts of it, but do not give in detail the method of application.

The splint is made of a single piece of No. 2 wire, bent as shown in diagram. A A^1 is four inches and rests below the sole of the foot. The angle at B B^1 is just enough to give sufficient flexion of the knee for comfort. A^1B^1 and A B are each twenty-two inches. B^1 C^1 and BC each twenty inches, with a slight upward curve near C^1 so that the wire clears the pubes. MM^1 is a bow of No. 2 wire that may be slid up and down the sides of the splint, its purpose being to keep the distance between C and C^1 such as will permit the upper part of the thigh to rest between them, while the bow itself will clear the thigh anteriorly. D, F, G, H, are hooks fitting the splint fairly snugly but movable. D E G and F E H are cords of pliable small rope of equal length attached by their ends to the hooks just mentioned. The pulley I is fastened to the ceiling at such a point, if the ceiling is from nine to twelve feet high, that a perpendicular from the pulley will fall seven to ten inches distally to the sole of the foot. In children this distance should be somewhat greater. If it is not possible to attach the pulley to the ceiling it can be attached to a frame passing up over the foot of the bedstead. E K is a cord looped at the end E around the cords D E G and F E H. The other end of this cord is passed through a hole in the wooden block T, then over the pulley, and finally through the block T again, as indicated in the diagram. T is a block of wood about two inches wide, one-half inch thick and six inches long, with holes in each end to allow the passage of the



cord, which should go in the direction indicated to give friction for retaining in position. When T is slid down the cord it lifts the splint and the lower extremity clear of the bed.

To apply the splint, place the thigh in an approximately normal position. Apply rubber adhesive plaster, as in Buck's extension. Place the splint about the lower extremity, both the splint and the extremity lying on the bed. The cord passing through the spreader of Buck's extension is then tied to AA^1 short enough so that BB^1 will be at the bend of the knee. Pin an end of a three or four-inch-wide strip of muslin around the side of the splint at the lower end; pass the strip under the heel and pin the other end

necrosis, more rapid in the under-nourished. The cells, which are derived from the blood, are, in general, classified under three heads. We have the small, round, white cell, the epitheloid, fatty cells, and the giant cell. The tendency of the tubercle, in the average case of consumption, is to undergo central necrosis, but where there is a tendency to recover a variable amount of connective tissue is formed.

The source of this connective tissue must, necessarily, be from the nutrition of the blood, and upon this greatly depends as to whether the tubercle shall undergo connective tissue change, and thus be cured. Cavities of the lung are formed in chronic phthisis by the weakening and dilatation of inflamed bronchi, and by the necrosis of inflamed lung tissue. The tubercle forms cavities from its own necrosis and the necrosis of surrounding inflamed tissue.

Let us now mention, more particularly, the pathology of the lung which comes from nature's efforts to surround the disease and to repair and replace the damaged lung. Tissue changes take place wherever the bacilli grow, which consists principally in cellular increase and the formation of epitheloid and giant cells, held by fibers of connective tissue, or there may be an inflammatory small cell infiltration, or an exudation of serum, fibrin, and red and white blood corpuscles, which change may occur singly or in combination. Sometimes the entire tubercle undergoes connective tissue changes, or if the patient is not so fortunate, his resisting power being good, though somewhat inferior, the formation of a connective tissue capsule offers great resistance to the caseation and breaking down of lung tissues. The resistance built up by the body around a tubercle and around a cavity are similar in construction and formation, and there is a unity of resemblance in the healing processes presented in the various forms of phthisis and tuberculosis which seems to correspond in its completeness to the amount of nutrition in the system. In the weakened under-nourished patient the advances of the disease are more rapid, and the resistance and reparative processes lessen; on the other hand, in the partially well-nourished patient, who is living out of doors and with a good appetite, the resisting powers and reparative forces take place to a greater extent and often overcome the disease.

From where do these cells and connective tissue come? Various opinions have been held, and where there are so many opinions there is uncertainty, but they can only come from one place, the blood, and if the blood is poor in nutrition, poor in cell activity, poor in fat and other constituents, then tuberculosis advances rapidly, for nature has not the means at her disposal to overcome the disease; on the other hand, if we furnish this nutrition through subcutaneous injections of oil (since the patient will rarely eat sufficient fats, and if he does they may not be absorbed until his digestion is trained), together with a proper diet, we have the material for the cure of the disease, since oil injected subcutaneously increases the growth of all the cellular constituents of the blood and furnishes material for the formation of connective tissue, and for the nutrition of the lung. We can now see how subcutaneous injections of oil meet every pathological condition of tuberculosis in a physiological manner and according to nature's immutable laws. The proof of their value is found in the fact that they cure, and thus proves all that we have said in theory.

Protection for the General Practitioner's Hands.

BY H. L. WHITENER, M. D.,
St. Louis, Mo.

Constantly reading new methods for the preparation of the hands before an operation, which are similar to the one below, led me to write what follows:

Take, for example, from "Kelly's New Operative Gynecology," where he advises:

"First, the hands and forearms be vigorously scrubbed for ten minutes with a brush, using common brown kitchen soap or green soap and hot water. Particular attention must be given to scrubbing the surfaces between the fingers, and to the nails, which must not be more than one mm. in length. The most vigorous efforts in washing must be devoted to the spaces

beneath and about the nails. The water should be as warm as can be comfortably borne, and either constantly changed with fresh water running in, or poured out and changed completely four or five times. The duration of this important step must not be measured by guessing; a clock must stand directly over the wash-basins and nurses (for the first three months) should be required to spend not less than fifteen minutes in cleansing their hands. After the experience in washing thus gained, the time may be reduced to ten minutes. Although the hands and arms now appear to be clean, they are not aseptic, for cultures taken from beneath the nails and from the skin will develop colonies of micrococci, often in large number, and, in spite of any washing, however prolonged and thorough.

"Second, the hands thus mechanically cleaned and softened, are next immersed in a hot, saturated solution of permanganate of potassium until stained a deep mahogany color.

"Third, they are then immersed at once in a saturated solution of oxalic acid, which decolorizes and completely sterilizes them. The oxalic acid solution should be as warm as can be conveniently borne.

"Fourth, the oxalic acid may be removed by rinsing the hands in warm water, but it is better for this purpose to keep on hand a dish of sterilized lime water which at once precipitates the oxalate of lime."

Now, we see it is impossible to sterilize the hands, even by immersion in permanganate and then decolorized in oxalic acid, and by soaking in a strong bichloride of from one one-thousandth to one five-hundredth, then why not adopt a method by which our hands are not subjected to all this heroic treatment, and which has, by experience, even proven to yield equally as good results as any method, and has the great advantage to the general practitioner of allowing him to do his operative, office and general work, and at the same time keep his hands in a normal healthy condition. For if one follows such a method, and has any operative work, he will be fortunate if his hands do not become rough, eczematic and full of cracks, thus rendering him thoroughly unfit for operative and general work. It was my experience, having a large general practice, and at the same time attending to my surgical work in the hospital after two or three years, to get my hands in such a state from a stubborn dermatitis, that I was incapacitated from doing any surgery for several months. Since then I have adopted the following methods of preparing the hands and the patients.

First, the hands are washed in running water with castile soap and a piece of gauze used, instead of a nail brush, care being taken to keep the nails short and cleaned with a nail cleaner, and using the gauze, which removes the loose dirt and epithelium.

Second, they are then rinsed in sterilized salt solution, using four ounces of salt to the quart, where again they are washed with a fresh piece of gauze.

Third, thoroughly dry with a sterilized towel, and then put on sterilized gloves of the better grade of white undertakers' or waiters' gloves, over these put on a thin rubber glove that has been properly sterilized. This has only one disadvantage, and that is the sense of touch is not so acute, but it compels one to use the eye, which is the better and more thorough way of operating. The patient is treated in the usual manner, of shaving, thoroughly scrubbing with soap and water, again washed with soap and water, irrigated off with bichloride, one one-thousandth, rinsed with alcohol and again with bichloride, one one-thousandth, and field of operation thus covered with bichloride towel, and the surrounding parts with heavy towel, over which is spread a sterilized piece of rubber sheeting, over this a bichloride towel, and lastly, a large sheet, sufficiently large to cover the whole patient, with a fenestra or slit over the line of incision.

After three hundred and two laparotomies, mostly gynecological, and with only two deaths—one from streptococcal tubal infection, where the abscess broke, and one from a hysterectomy, where cumolized catgut was used to tie the uterine arteries, where ligature slipped, with resulting hemorrhage—with only three-stitch abscess, when the stitches had to be removed,

one on the fifth and one on the ninth and eleventh days, respectively, I feel perfectly safe in saying that these methods have yielded most gratifying results in my hands, and under these methods my hands have greatly improved and I am not annoyed, as before, after an operation.

2009 East Grand Avenue.

[Written for the MEDICAL BRIEF.]

Medical Wonders and Medical Blunders—A Story of Facts.

BY M. J. RODERMUND, M. D.,
Milwaukee, Wis.

CHAPTER XXIV.

THE BIG FOUR—BREATHING, EATING, SLEEPING AND WORKING.

It has, no doubt, been apparent to many readers of the BRIEF that I have not stopped to inquire whether the doctrines that I have espoused harmonize or conflict with orthodoxy, heterodoxy, or any doxy at all. The only thought I have tried to keep in mind was whether or not what I have explained in this series of articles has been in harmony with nature's laws. These laws never lie, at least, no one has, as yet, caught them napping. Man can not change them and no man will ever be wise enough to cheat them. All I have stated in the previous chapters I have demonstrated to be true; therefore, it must follow that the medical fraternity are absolutely wrong in respect to the cause of disease, and the right mode of preventing or treating the same, because their notions conflict with nature's laws, therefore must be injurious and useless.

It matters not if you have faith in the Holy Trinity or whether you have faith in spirits, Christian Science, or the orthodox medical frauds, all this will not annul the punishment if you violate natural law; whether sumptuous courts, chanting priests, or tearful penitents, it makes no difference to nature whether you are a Christian or a scoundrel, the natural law penalties will be precisely the same. This being true, it behooves all mankind to obey these laws, either by instinct or education, or suffer the consequences. The beauty of it all is that the Creator's laws are so benevolent in their design that all can follow them with the greatest ease, whether he be a scholar or not. The fact is, man must abide by the "big four" in harmony with the laws of his body and his environment, namely, breathing, eating, sleeping and working, to be healthy and live a long life.

It seems somewhat ludicrous to make such a statement as the above in the twentieth century, where the claims are made of such wonderful advance and medical progress. I admit great progress, but most of this progress has been in going rapidly away from the truth. In fact, the barbarians and the uncivilized nations are nearer to nature to-day than we are, barring a few of the improved hygienic conditions which we enjoy at present. As before stated, for all practical purposes, obeying the "big four," weighted by the law of balance and adapted to each individual, is all there is to it after birth in order that we may live out our allotted time inherent in our constitutions.

I am sorry to say that our present medical philosophy, education and medication is far more injurious to the health and constitutions of our race than were the practices of the dark ages. We are to-day depending upon various pie-hunting medical and political gods to preserve the public health, who seem to know as little about these "big four" laws as some of the men elected to Congress know about the Federal Constitution, or Calvin's confession of faith. By chasing the harmless microbes and instilling the public mind with the fear of contagion, and the benefits of quarantine and vaccination, we have quite lost sight of the enormous meaning of the "big four."

No thinking man will disagree with me when I say that we should eat only to furnish the body with the proper elements for nourishment. Only with this object in view should we eat. But instead, many and various are the reasons for satisfying the appetite, especially among civilized people. We often eat from force of habit, for society's sake, to tickle the palate, etc. The question as to *why* we eat goes far towards asserting the *how*. We should, in eating, chew the food until it is thoroughly mixed with the saliva, whether you do this fast or

slow is, as a rule, of little importance. In this way we get the richness in taste and full nutritive value out of the food. Do not make a race track of your food-pipe while eating. Eat only when you are hungry and of that which is ordinarily called plain food, and eat them as near like nature made them as possible, and you will have little trouble having it adjust itself to the wants of the body. Do not eat when you are very tired or excited, worried or angry. If you must eat under these conditions, it should by all means be only a portion of the meal. Remember that the "big four" must always be considered and weighted in all their parts and not taken singly.

Next comes breathing, through which we furnish, from the universal dynamo, the power that circulates the blood and oxidizes or burns up the food eaten, and without which the food would be of little value; any more than it would be to furnish a stove or furnace with the best of fuel without a good air draught. Failing to recognize this point is what deceives so many people who pay particular attention to their food and but little or no attention to furnishing the body with the proper amount of oxygen to burn it up. So we see breathing good air and having normal blood to take up the oxygen is even more important than eating itself. Just as poor fuel with a good air draught will often give a better fire and produce less ashes, smoke and clinkers than will good fuel with a poor air draught. This, in a short time, causes excessive accumulation of ashes, smoke and clinkers in the human system, and clogs up its grates, flues, and chimneys, which ordinarily are termed the skin, kidneys, and lungs. When this universal air draught or, in other words, the atmospheric conditions, together with our own acts, are such as check the air draught of the human furnace, it will lower the fires of life and will retard elimination. Those whose flues, pipes and chimneys are not kept clean will accumulate enough waste matter to clog them up, and when this occurs we will hear of disease bobbing up in the most favorable localities, and we call it an epidemic of small-pox, scarlet fever, diphtheria, etc. The individual conditions, age, environments, and the kind of work done, will determine which one of these diseases will manifest itself.

Small-pox usually breaks out among those who produce large quantities of urea, uric acid, etc. This is why small-pox usually appears first among the hard-working laboring men, or the dissipater, Is this not a logical explanation of the cause of epidemics? It is common sense and will prove true in every instance when put to the test. Then, what more do you want? Again, we see that in order to prove the cause of epidemics, we must take every phase of the "big four" into consideration.

Under the head of working, we must include everything that man does that will exhaust energy. In a sentence, learn to estimate your physical capacity, then select the proper kind of work or vocation particularly adapted to your capacity and work within the limits of this capacity, whether it be mental or muscular work, or both. This, in a nutshell, tells it all. Yet a small volume could be written to elaborate the above thought in detail.

The modern revival of the dogma of the nobleness of work has been pushed too far. It has become almost as pernicious and extreme as the old and now unfashionable worshipers of idleness. There is no more deep-rooted cause for disease in this country than overwork or working beyond one's capacity. The employer crowds his workmen beyond natural endurance, wrecking their constitutions; while, on the other hand, the employer very often works even harder, and in the end suffers even more than his laborers. This condition of affairs must be stopped, as it is deteriorating our nation's physical capacity. I believe in a harmonious and pleasing relation between the employee and employer, each giving a little attention to each other's needs and requirements. There can be no doubt that such little indulgences and considerations would be repaid with compound interest. A little foresight would reveal the fact that an overworked man is not as profitable as a man who keeps well rested.

Professional and business life is becoming literally a battle, and men are falling by the hundreds in the thick of the fight.

Nature is bound to disclose these abuses in some form or other. Nature is a great disclosure of unfinished truth. Her facts shine out and so do her principles. She will never falsify herself, nor permit any of her children to do so. Nature compels all to fly her flag at masthead, whether it be a flag signifying health or disease. Nature labels all her children, and these labels can not be washed out or counterfeited.

The human being, like any other machine, will wear better and longer if worked and kept properly oiled than if it is allowed to stand idle and rust. A machine run beyond its capacity, or run when there is irritation or friction, will soon wear out at the point of friction, which may make the whole machine useless. It is just so with the human machine. Irritation and friction will wear it out faster and in a shorter time than smooth and hard work would in many years. These facts are very important, and there is no way of receiving any benefit from them except by each individual being educated to understand his own machine, finding whether or not it has any weak points and to work and regulate his life in accordance to his capacity. This capacity is no stronger than his weakest organ or part. The law that action determines structure must not be overlooked in nature, and where parents are educated to understand these principles and to apply them, they can by judicious exercise improve the weak organs or parts in their offspring, to a large degree, by keeping the strong ones in the background. But nowadays parents are too apt to keep the strong traits of their children active, to show the neighbors how smart they are. Of course, as I stated in the December article, it is still better to correctly abide by nature's marriage laws, by mating properly and carefully, preparing the germ and mother soil, and thus have well-balanced children from birth. Then, with a little care, there would be very little or no sickness all through life.

I can not conceive of anything that can be put in the English language that should be more earnestly sought and more thoroughly established among all mankind than the proper education of the young in our schools, and to keep it before the people in after-life, so they will never forget the necessity of understanding and applying these principles. Each one must apply them to himself or herself, in accordance with their own physical capacity and particular environment in which they live. To accomplish this, public sentiment and legislation should compel harmonious relations between the employer and employee, and especially a reorganization of our social status, which, I believe, does even more harm than the former. A few selfish and ambitious workers sometimes excuse their error, and say that life depends more upon the value and amount of work done than upon the number of years they might live. The short-sightedness of these men can be easily shown. If a man kills himself by overworking during a space of twenty years, it would be a rare instance if this same man could not have accomplished more in forty or fifty years, and at the same time enjoy a long life by making his laboring hours a pleasure instead of a drudgery. Another error committed by so many of our active men and women is that they will work at high speed for many years in order to live and enjoy the results of their labors. Both of these are injurious to health or a long life, because both are extreme measures. Labor and pleasure should go together in order to reap the benefits of either. A man who has been active through life and all of a sudden stops working altogether, will usually decline in health and cut his life short. Here again, we run up against the old law, the law of balance and proportion. In order to correctly measure your work by your physical capacity you must take the sum total of energy used, mentally or physically, in pleasure or sorrow, in social or sexual life. In short, every act and thought uses up energy; moderation in all is conducive to health. Idleness is as productive of disease as overwork. A reasonable balance in all things is nature's demand.

Sleeping.—You are a sick person every night of your life. The difference between going to bed tired at night and a patient sick of typhoid fever, small-pox, and the like, is one of degree only.

Whether this thought was worth the labor or not, it took me two years to frame it into a sentence. I wanted a sentence that would fairly express the primary cause of disease in a nutshell. It shows how little in the past we have realized the value of sleep. To carefully follow out the full meaning of this sentence would practically mean the abolishing of disease, especially those of the zymotic and nervous varieties.

Every form of animal life requires sleep. Love of sleep is quite as strong an instinct as love of food, because food nourishes the body, and sleep recuperates or cures it. We should get up well every morning. If we do not, we are certain to gradually run behind in our physical bank account. This proves that sleeping is quite as important as eating. The luxury of sound sleep is one of the greatest means given to man or beast for restoring and invigorating the whole system. No one should allow business or anything else to curtail this luxury, and parents should promote it in children, instead of drumming them out of bed early. Indeed, the best way to do the greatest day's work possible is to get a complete sleep the night before. Work with head or hand, or both if you wish to, as long as you can sleep sufficiently, but be sure and stop as soon as your sleep departs or ultimate breakdown will surely follow. Keeping well slept out and rested will add immensely to your capacity to enjoy, endure and accomplish much, and, at the same time it promotes all the other life functions. The excessive accumulation of waste products during the day, and the loss of energy in excess of production, should be recuperated and balanced up by rest and sleep before the next day's work is begun.

Excitement of the brain and the nervous system, due to mental troubles and over-exertion, are common in this country and prevent a due supply of sleep. If you would but stop and think that we are using up the very best of physical ammunition upon game that is not worth it, there would be much more splendid energy reserved, instead of using it up in anger and passions upon other people. We should sharpen our sleeping appetite and prepare ourselves mentally and physically for this delightful repast and grand restorer of exhausted energy. Medicines are of little value when compared to good sleep; therefore, it is bad practice to awaken a patient to give medicine. When a sick patient is getting good, natural sleep, it is the very best sign. Being disturbed when once asleep is as bad as a shock when awake.

Many physicians are killing themselves by unnecessary night work, just because there is more money in it. Nearly every night call can be avoided, because most of them are unnecessary. A patient will surely feel worse after midnight, and the physician is called. In most cases he knows it is unnecessary, but he wants the fee. I know from experience that night calls can be made to be the exception. I would tell the family and patient how he or she would feel during the night and not to become alarmed, as they might look for those symptoms and getting me out at midnight would do nothing but make them expense. I have seen many a physician go to his grave in the prime of life on account of the greed of trying to get in all the night calls possible. We rarely find that the laborer wants for sleep. It is the mental worker or the person who keeps himself or his nervous system unnecessarily irritated by letting every little thing annoy him and thus prevent sleep. A man who is engaged in strenuous mental labors and keeps his brain congested, is certain to have wakeful hours until the circulation is balanced. He should understand these little rules and laws, and by some cheerful diversion, such as amusing himself with his family, or otherwise, bring about a balance in the circulation. This is especially valuable when combined with a brisk walk and cheerful mental inclinations. The stomach, when filled with food, will attract large quantities of blood, which is necessary to carry out its functions. When the muscles are active they likewise attract large quantities of blood. These are well-known facts, and the medical profession insist that the blood is propelled by the heart. We are certainly a very thinking and philosophical class of men.

Some people in this country are afflicted with small-pox because they are too lazy

to work enough to keep the peripheral circulation active, and thereby cause internal congestion, which leaves the skin an easy prey to the various atmospheric changes. An active skin circulation is essential to health. Impressing our nervous and irritable women with the necessity of understanding and following these simple laws of balance would do a hundred-fold more to restore the health of peevish and nervous wrecks than will drugs. Many people are becoming educated to the necessity of airing their sleeping rooms and living rooms, and the value of circulation air, but it is astoundingly neglected by a large percentage of the public, even at the present time. If the reasons were explained to the public why proper air is so necessary, that air is the power that circulates the blood, that it is the power that assists in eliminating the poisons from the body, we would hear much less of small-pox, and the other forms of the so-called contagious diseases. Of late years, this class of diseases is not very prevalent among the better classes, but many of the laboring people are still in the habit of keeping their houses closed up in order to save fuel; sometimes it is done through ignorance. When such a condition is combined with unfavorable atmospheric conditions, gradual accumulations must take place, and small-pox, scarlet fever, etc., are sure to break out in those localities. This being true, and it also being true that the medical profession claim to teach the public how to prevent disease, shows an inexcusable negligence or ignorance of the profession. The fact stares us in the face that if the profession would give the public what they actually claim to give them, more than one-half of the physicians would have to go out of business. These are two widely-separated and antagonistic propositions. I don't see how they can live together, any more than Divine love and the devil himself. I have always maintained that a separate organization should exist for the purpose of educating the people, and this body should see that the people were given the opportunity to live right and that they did live right. Then the physician's duty would be solely to properly treat those who through ignorance or negligence should violate the laws here set forth. No man is going into any kind of business and then stand in front of his store and demonstrate to the public that they can get along without buying his goods.

Ship Disinfection.

BY GEO. H. TICHENOR, JR., A. B., M. D.,

Former Medical Inspector and Yellow Fever Expert Louisiana State Board Health; Nominee of Nicaraguan Minister to United States for Membership in Yellow Fever Institute; Member of the Association of Officers and Surgeons of Confederate States Army and Navy, Etc. New Orleans, La.

(Continued from page 58.)

Since it is an admitted fact by scientists that the stegomyia fasciata is responsible for transmitting yellow fever from the sick to susceptible individuals, and that malaria is due to a special species of mosquitoes, it is evident that the regulations concerning ship disinfection will, sooner or later, have to be changed. My own experience in the last epidemic in Louisiana has proven, to my mind, very conclusively that sulphur and pyrethrum are almost worthless drugs for fumigation. While I do not deny the fact that mosquitoes can be effectually destroyed by these drugs with proper precautions, yet in the case of an epidemic, or where rapid work is necessary as, for instance, ships in transit, it is almost impossible for this to be done properly with an ignorant or negligent crew of fumigators. The frequent complaints of ship owners and property owners of damage to fabrics or colors, etc., done by regularly employed fumigators, is a well-appreciated fact by anyone who has ever been a health officer.

Another disagreeable feature confronts the health officer in regard to ship disinfection—mosquitoes are carried by the wind for the distance of ten miles from shore. I have observed this fact, although it is disputed by many. I have been on ships coming into port which had no mosquitoes on board, and have observed a drove of the stegomyia fasciata blown to the ship, which at the time was fifteen

miles from shore, according to the ship's "log."

Considering everything, it appears to me that pine tar is the best disinfectant that can be used.

During the last epidemic pine logs, where they were plentiful, were burned in infected quarters by me. My experiments have proven to me that pine tar was efficient. There is a practical point to be considered in its use and that is unless it is well spread out over the surface of a good fire only a portion will be volatilized and the remainder will char and catch fire, burning with a dense, sooty smoke, a feature which would be disagreeable.

The Practice of Homeopathy.

BY N. SISCA, M. D.,
Killarney, Queensland, Australia.

(Continued from Page 64.)

VIII.

Let us now see, in a small way, what are the practical bearings of the principle *similia similibus* on the process of building up the so-called "pathogenesis" of a given drug, or, in other words, on the process of ascertaining from the homeopathic point of view and for homeopathic uses the therapeutic properties of a drug, such, for instance, as carbolic acid, which is common to both schools.

Taking Ringer's "Handbook of Therapeutics" as the authority for our side, we find that carbolic acid is first of all an antiseptic, which accounts for its manifold uses in various dilutions as a topical application to the throat, to gangrenous and ill-smelling sores, etc., as a wash in sloughs of the mouth, for injection into the cavities of large abscesses, etc. Next we find it recommended as a local anesthetic in burns, erysipelas, pruritus, etc., and finally as a remedy for inhalation in bronchitis. As to its value for internal use, we are told that it is an indifferent antipyretic, and also that taken in drop doses it prevents decomposition of the blood. From other sources we learn that it is given to check sickness, to arrest diarrhea, to remove intestinal worms, and that it is helpful in whooping cough. Many years ago it was suggested that it might be of service as an intestinal antiseptic in typhoid, and of late years it has been recommended externally in smallpox and hypodermically as a remedy for tetanus and as a local analgesic.

Turning now to homeopathy, we find on the one hand that homeopaths make as much use as we do of the antiseptic and anesthetic properties of the acid, and on the other that the many cases of carbolic poisoning which, from a general therapeutic point of view, have been, as it were, a dead letter to us, have instead been a source of much information to them, and that not only they have not been slow in turning it to good account, but have also confirmed and supplemented it with their provings. Thus we find that their "pathogenesis" of carbolic acid has been built up from symptoms collected from twenty cases of poisoning and as many provings, and those symptoms are arranged in the following "schematic' form:

Mind—Symptoms from poisonings. "The man uttered a cry, and tumbled off his chair, unconscious * * * stertor, agitation, groaning * * * respiration irregular, labored, pulse not quick, very compressible and occasionally intermittent, sensibility almost entirely lost. At the end of two hours recovered consciousness, but remembered nothing of what had passed." "I found him (after three hours' exposure to the fumes of strong carbolic acid) in violent convulsions, with trismus and blood passing from the mouth in consequence of the teeth having wounded the tongue; quite comatose, face and neck livid, breathing stertorous, extremities and surface of body cold, pulse scarcely perceptible," etc., etc.

As these symptoms make up a very fair picture of an epileptic fit, in obedience to their "law of similars," homeopaths recommend carbolic acid as a remedy for epilepsy.

Head—As the cranial symptoms produced by the acid are very similar to the symptoms of migraine, it is accordingly put down as a remedy for migraine.

Throat—Although in poisoning the effects of the acid on the throat are no

doubt chemical, yet the results of the provings show that in fairly large doses it causes a certain amount of congestion of the pharynx and the trachea, consequently it should, in small doses, be of service in congestion of those organs.

Chest—As both provings and poisonings point decidedly to pneumonia, the acid is strongly recommended as a remedy for the critical stage of that disease.

Heart—Large doses, as in poisonings, render the pulse almost imperceptible, fluttering and thready; infinitesimal doses increase its frequency.

Kidneys—Carbolic acid has caused acute nephritis, consequently it should also be a remedy for it.

Digestive Organs—The most common effects of moderate doses on the stomach seem to be nausea, very frequently followed by actual vomiting, both of which symptoms should be curable by small doses.

Skin—Large doses cause general irritation, which small doses should relieve or cure.

Genital Organs—Substantial doses in the male provers caused weakness, relaxation and nocturnal emissions, for which complaints small doses ought to be useful.

As in a surgical case, carbolic dressing caused something similar to pyemia, the acid in small doses should be thought of in treating pyemic conditions.

Here, then, we have a fairly typical instance of the method followed by homeopaths in trying to find out what a drug is good for. So far as we are concerned, all that we know of carbolic acid as a medicine does not practically go far beyond the limits of its uses as a remedy for external and topical applications. We certainly have records of *post-mortem* examinations in cases of carbolic poisoning, but our interest in them has always been limited to their pathological and medico-legal aspects. Most of us are also more or less familiar with the symptoms observed in those cases, but however much there might have been in them for us to learn from a general therapeutic point of view, we have not, and could not have, learned it, merely because we have never even suspected that there could be anything in them worth learning beyond what is the direct concern of pathology or forensic medicine.

But we have seen that it is not so with our friends, the homeopaths. Their *Materia Medica* would be the poorer by a good half without the large number of symptoms they have been able to collect from poisonings of all sorts, whether it be carbolic acid or aconite, arsenicum or belladonna, phosphorus or plumbum. And if we want to know how it is that they have found therapeutic uses for carbolic acid which we have not; what it is that has given them the clue which we have never had, and why a case of poisoning should be an open book to them, while from the point of view of general therapeutics it is a sealed one to us; the answer is: because the principle *similia similibus curantur* teaches them to look for symptoms everywnere, more especially in cases of poisoning, where the objective and subjective symptoms are the surest and most reliable landmarks in what they call the "pathogenic power" of a drug.

[Written for the MEDICAL BRIEF.]

Influenza and Typhus Fever.

BY JOSEPH D. HARRIGAN, M. D.,
New York City.

In a paper recently on "Deadly Parallels in Disease," the writer compared the symptoms found in cholera with those found in influenza, and drew attention to the remarkable analogy existing between the two sets of symptoms.

Mention was made of the fact that a strain of influenza ran through all the epidemic diseases.

A change in the sequence of symptomatic happenings may mask this relationship at times, but can not eliminate it. In a manner as decidedly marked as in cholera do the symptoms of typhus fever exhibit this relationship to influenza. A comparison of the symptoms in both diseases will prove as interesting, I have no doubt, as that between influenza and cholera.

With regard to typhus fever, Lebert says (Ziemsen's Cyclopedia, Vol. I):

"In the beginning, a catarrh of the conjunctiva or of the buccal mucous mem-

brane is more common; a few days later a low degree of bronchial catarrh takes place, at times accompanied by laryngeal catarrh, hoarseness, and difficulty in swallowing. In rare cases I have seen a severe bronchitis appear as the main feature of the disease, just as in the severe bronchitic forms of typhoid fever. The congestive febrile stage at the beginning of this disease is accompanied by manifold catarrhs, analogous to the acute exanthematous affections."

The first stage of the disease may be called a congestive-febrile one. When the fever appears, the skin is hot, often slightly reddened, especially that of the head and face, the cheeks being red and swollen, the eyes being somewhat red. During this period the patient complains of an extremely severe and constant headache. Noises in the ear are a frequent symptom. The pains in the limbs and joints are more severe than in typhoid fever. Symptoms of catarrh are not uncommon, as sneezing and slight sore throat. The pronounced redness and swelling of the face and eyes during the first week often end, in the latter instance, in a conjunctivitis.

In addition to the accelerated respiration due to the fever, abundant râles are observed in the chest, with tolerable constancy, and the patient is troubled with a frequent dry cough, accompanied at times by a scanty, mucous expectoration. Swallowing is rendered difficult on account of dryness of the pharynx.

I have found, almost constantly, affections of the organs of respiration similar to those occurring in typhoid fever, though less in degree. Bronchitis usually occurs during the first week; the cough is slight, there is little or no expectoration, no difficulty of respiration, and one hears merely isolated, rather sibilant râles.

During the second week the bronchitis may become diffused, terminate in bronchiolitis, connected with atelectasis, and the condensation, without infiltration, of larger portions of the lungs. In such cases the symptoms are very decided, may even predominate, so that one might speak of a bronchial typhus. Indeed, I have seen cases of extensive purulent bronchitis where the eruption was absent, and where the diagnosis was established merely by the range of temperature and the enlargement of the spleen. A considerable number of the fatal cases owe their unfavorable course to a bronchiolitis, broncho-pneumonia, or diffuse pneumonia, while extensive pleurisy and gangrene of the lungs are rare. Of laryngeal affections I have seen only, though repeatedly, simple catarrh, accompanied by hoarseness. In many epidemics a diphtheritic croup has often been observed.

Secondary diphtheritis of the pharynx and upper part of the respiratory tract, also ulcers of the larynx, are among the rarer "complications."

"Parotitis occurs early in many epidemics, likewise often, even in twenty per cent of the cases." (Schilling, New York, 1852.) Before proceeding to a consideration of the symptoms occurring in influenza, almost identical, if not absolutely so with the above-mentioned symptoms of typhus fever, I wish to file a most strenuous objection to the custom of terming the various localizations of the disease processes in the affections under consideration as "complications."

I have repeatedly spoken of this misleading term in various papers. Reiterating what I have said at different times, I desire to repeat with as much emphasis as I can, that we are no more justified in calling these intercurrent localization of disease "complications," than we would be in using the same term with reference to the localizations of tuberculosis, scrofula, syphilis, scorbutus, or any other of the constitutional diseases.

These so-called "complications" should properly be referred to, as *e. g.*, typhous laryngitis, influenzic laryngitis, or typhus bronchitis, influenzic bronchitis, etc., etc., as the case might be, just as we speak of tuberculous laryngitis, syphilitic laryngitis, scrofulous periostitis, etc. They are an integral part of the whole process transpiring, and should be so regarded, and not as merely local affections interjected at times into the case, as this term would mislead us to think.

Taking up the symptoms of influenza, I find it necessary to cover almost the same ground, and follow the same footprints that I made in comparing influenza with cholera.

Zuelzer, in his article on "Influenza" (Ziemsen's Cyclopedia, Vol. II.), says:

"Almost invariably a more or less considerable portion of the mucous membrane, especially that of the respiratory organs, is affected, and this is the characteristic feature of the disease. The symptoms are essentially of a catarrhal nature. We find most frequently marked cold in the head, with considerable discharge from the nose and, sometimes, epistaxis; redness of the conjunctiva, with abundant lachrymation; catarrh of the mucous membrane of the throat, larynx and bronchi; also sore throat, difficulty of swallowing, hoarseness, tendency to cough, and a burning or tickling sensation in the throat. The mucous membrane of the cavities of the nose, mouth and pharynx are generally found reddened, and the tonsils swollen."

At the very beginning there sets in a very tormenting, convulsive, dry cough, which becomes paroxysmal, especially in the evening and at night. The sputa are very scanty and muco-serous. Auscultation frequently reveals sonorous, or in places, crepitant, râles. There also occur cases where the auscultatory phenomena are very insignificant or absolutely wanting.

Frequently, there are only hyperemia of the lungs, and intense bronchitis, but, also frequently, catarrhal pneumonias, which are to be considered as a continuation of the bronchitis into the vesicles of the lungs.

Besides this, croupous pneumonias also occur, and are said especially to involve the period of convalescence. These "complications" appear not to be unusual.

Pleurisy, without accompanying inflammation of the lungs, appears to be rare. Croup and false croup are, sometimes, present. Parotitis, with salivation, is sometimes observed.

The remarkable similarity of symptoms hitherto presented must certainly appeal to the fair-minded observer as due to something more than mere accident, and must compel us to consider them as essentials of both diseases.

Proceeding to a consideration of the digestive symptoms in typhus, we find, according to Lebert:

"The affection of the digestive organs is, for the most part, influenced by the severity of the fever, and consists rather of disturbances of function, or of catarrhal conditions of the pharynx, stomach, and intestinal canal.

"Severe diphtheritic complications in the pharynx, at times of a destructive, almost gangrenous character, occur sometimes in typhus wards, particularly where many cases are crowded together in confined spaces.

"Diarrhea is absent in many epidemics, in others frequent. When there is no diarrhea there may be a tendency to constipation in some, while among others the bowels are regular. Diphtheritic inflammation of the colon may occur as a rare, secondary disease. It seems to me very remarkable that Griesinger should state the splenic enlargement is absent in many epidemics, as found, for instance, by Oesterlen in the epidemic at Dorpat. The absence of enlargement in one-fourth of the cases proves that this lesion is not so essential to typhus as to typhoid fever. But that the splenic enlargement should be absent in entire epidemics is, to say the least, remarkable."

Passing now to influenza, we find, according to Zuelzer:

"The mucous membrane of the digestive organs is likewise affected in many cases, although generally not to so high a degree. Loss of appetite, increased thirst, a coated tongue, a bad, pasty taste, sensitiveness of the epigastrium, and, not infrequently, colicky pains and diarrhea, or nausea and vomiting, accompany the disease.

"In other cases there is persistent constipation."

Taking up the nervous and other symptoms in typhus fever, we find that, according to Lebert:

"In febricula and in the milder cases the nervous system is but slightly affected; but, on the average, typhus produces earlier and more decidedly than typhoid fever, great prostration of the strength, subjective sensations of extreme debility, indistinct speech, twitchings of the limbs, and protruded tongue, together with every transition, from dullness to drowsiness, sleep, stupor, and coma. Delirum is usually of a mild type, only at times violent and wild.

"Curiously contrasted with the somnolent condition, especially during the second week, and by no means rare, is the decided hyperesthesia of the entire surface of the body.

"The headache is marked, as in typhoid fever, and ceases after a few days, while the pains in the back and limbs during the first few days of the disease are much more pronounced and severe than in typhoid fever.

"Giesinger rightly attributes the deafness to catarrh of the outer and middle ear. Spasms and convulsions are rare, though they are, apparently, more common in many epidemics."

Taking up, now, the nervous symptoms of influenza, according to Zuelzer, we find:

"The prostration of the strength is very great from the beginning; the patients feel exceedingly weak and exhausted, and soon take to the bed. They complain of severe headache, especially in the forehead, in the neighborhood of the root of the nose, and in the sockets of the eyes. It is often stated that the pains are experienced in the passages and cavities of the head ' lined by the Schneiderian mucous membrane and its processes, especially in the frontal sinuses, but sometimes also in the antrum of Highmore, the nasal ducts, the eustachian tubes, the drum of the ear, etc.

"In some cases the whole head is involved, or there is a marked hyperesthesia of the skin of the head and neck. We regularly find, together with considerable depression, very severe pains in the limbs. At times they are limited to particular muscles, tendons, or ligaments, or are perceived as a generally diffused hyperesthesia over the whole body.

"In addition to these, there also occur in influenza several nervous symptoms, as happened very often in the epidemics of 1782, 1837, and others. Patients are often unusually restless, sleepless and anxious. If they get up they are frequently dizzy. Mild delirium occurs not infrequently, but more intense forms are also observed. In contradistinction to this, somnolent states show themselves in some epidemics; in the epidemic of 1712, which was specially marked by this, the disease acquired the name of sleep sickness, from the frequent occurrence of this symptom.

"In the more severe forms there were sometimes observed painful cramps in the calves, and twitchings of single muscles, trembling of the hands, subsultus tendinum, etc.

"The severity of the attack is also evidenced by the change in the expression of the countenance. The patients have a suffering, anxious and depressed look. According to Landouzy and Biermer, they sometimes even have a typhoid appearance, while in other cases the face is only a little altered."

Carefully comparing the two sets of symptoms, so far presented, I have no doubt but that the reader will perceive that there is not one symptom exhibited in the one disease that is not duplicated in the other. It is true that the symptoms are not always as intensely developed in influenza as in typhus; that is, taking an average of the severity of the two diseases, but neither are the symptoms found in the various epidemics of either disease identically the same.

Cases of typhus in certain epidemics, from a perusal of the symptomatology of them, must have been so unmistakably identical with cases of influenza that it would be ridiculous to regard them as anything else but the same disease. However, leaving this aside for the present, let us take up the so-called typhus eruption, and compare it with the eruption found in influenza.

Lebert says:

"In spite of the numerous peculiarities of the various forms of typhus fever, petechial typhus, more than all the others, shows an additional point of contact with the infectious exanthemata, and I have often called the attention of the students in the ward to the resemblance between a fresh and extensive typhus eruption and that of measles.

"In the second half of the first week, and particularly towards its close, the characteristic eruption generally appears; it is by no means rare for it to occur at the end of the week, and I would call particular attention to the fact that I have seen cases of typhus fever in which there was no rash at all.

"The roseola of the exanthematic form of typhus does not perceptibly differ in quality from that of typhoid fever. The

eruption 'is much more abundant on the chest, abdomen, back, extremities, and even on the face,' than that of typhoid."

Professor Lebert then proceeds to describe the characters of the eruption, which it is unnecessary to repeat here. Further on he says of this eruption: 'I must again protest against its possessing any specific character."

The different epidemics have, evidently, furnished numerous variations in the character of eruption developed, so much so in fact that it seems ridiculous almost to set very great store by it.

Now, with regard to the eruptions that have, at various times, developed in influenza, there seem to have been numerous varieties, exactly as in typhus fever.

Zuelzer says of them:

"The statements of the earlier observers about the 'complications' of influenza with exanthemata, such as miliaria, roseola, urticaria, petechiæ, scarlatinal spots, erysipelas, etc., seem to refer, as Biermer assumes, chiefly to miliaria and urticaria."

Whether this assumption of Biermer's is correct or not is unnecessary to discuss here. The fact is that observers to whom we must certainly grant intelligence, and, likewise, powers of scientific observation, have noted variations in the character of the eruption in influenza, and these variations run the entire gamut of similar variations that characterize the numerous forms of typhus fever, and that differ so widely in different epidemics.

Having thus briefly outlined the remarkable similarity of nine-tenths of the symptoms of the two diseases under consideration, it seems impossible to the writer to escape the conclusion that the one disease is founded upon the other, if, indeed, they are not identical.

To split hairs over the color of a few spots, their profuseness, or the reverse, their locality, their various characteristics, etc., when it is shown that they suffer wide variations in different epidemics, as likewise in different individuals in the same epidemic, seems to me anything but a scientific method of getting to the root of these diseases.

The same may be said as to the presence of or absence of enlargements of the spleen, acknowledged to be absent in one-fourth of the cases.

The one disease is certainly more severe than the other, but that appears to be the only important difference between them, and is easily explainable on the ground that in the one case there is much less in the active agent causing the disease in operation in the system, or else that the activity of the same agent is greater.

The result would be the same, a more intense development of the affection, as likewise a more profound involvement of the anatomy and greater interference with the physiological functions.

We have in syphilis a constitutional disease differing very widely, when viewed in its primary, secondary, or tertiary aspects, yet no one would dream of calling them different diseases.

It is exactly the same with epidemic disease. Where we find diseases in which the symptoms are almost exactly duplicated, it is impossible to escape the conclusion that there is a common basic groundwork upon which those diseases rest, and *that* one must be the foundation which exhibits its peculiarities throughout all the others.

What might be called the primary form in which epidemic disease of the character of typhus fever, cholera, etc., shows itself, finds no better expression for exhibiting its simple, foundation-like characteristics, than in the symptomatology of influenza.

Essentially a constitutional disease, liable to develop its peculiarities in any part of the body, wherever the blood supply and electric supply circulate, making its presence felt in places of least resistance, influenza shows itself primarily as a disease of mucous membranes.

It seems reasonable to consider, though, that the disease is not always limited to the mucous membranes.

Its transition into the deadliest of scourges from being only an extremely annoying affection, can readily be predicated on the basis of an overdose of the poison absorbed. No part of the system is exempt from its attacks, consequently its combinations of symptoms must be innumerable, each new combination offering material for extending the nomenclature of medical literature.

Other factors, no doubt, enter into the matter at times, each one enacting a certain part in transforming influenza from its original, more or less simple form, into complex varieties, but through all its protean aspects, it seems to me, that it should be incredibly easy for anyone looking beneath the mere surface of things, and not warped in his judgment by every little idiosyncrasy of the disease that might present itself, to immediately recognize it.

Influenza, entering, as it does, into the composition of many of the world-wide epidemic diseases, appears to be the unit among them, upon which they seem to be unmistakably based.

Having, thus far, in this article compared influenza with typhus fever, and in a previous article, as mentioned above, influenza with cholera, it will afford me great pleasure at some future time to take up other of the epidemic diseases and by the same method of comparison be successful in showing that influenza is the foundation and basic groundwork upon which they are all constructed.

Whether or not my efforts in this direction are justifiable, I leave to the judgment of my readers.

668 Lexington Avenue.

[Written for the MEDICAL BRIEF.]

An Unusual Criminal Case of Superficial and Deep Seated Gangrenous Inflammation of Forearm.

BY R. MENGER, M. D.,

San Antonio, Texas.

Of late years several cases of gangrenous inflammation came to my notice, caused either by insect or snake bite, with more or less loss of integumental tissue and large scar formations. But the case I wish to report more fully

No. 1.

happened some years ago, and as it was an unusually interesting one as to the cause of the gangrene, it is herewith submitted with several photo-illustrations which I happened to preserve and which I prepared during the healing process of the case.

A young lad was sent to my home office by a police officer, who stated that the lad had had his arm "burnt" by another companion "for the purpose of begging!" It happened during a very severe, cold winter, and it was a pitiful sight to be-

No. 2.

hold how the lad suffered and he had his entire arm wrapped up in dirty rags, emanating a most penetrating odor, which smelled like anything but rose oil. On unwrapping the arm a fearfully inflamed surface, covering nearly the entire forearm—from the wrist to near the elbow—presented itself, covered with gangrenous tissue products and pus.

On questioning the lad about how he got "burnt," he said his companion saturated a piece of rag with concentrated lye and spread it over the arm, for the sole purpose of aiding the lads in begging alms on the streets. (It was a case of "run-away" from parents who lived up North.)

No. 3.

After cleaning the entire inflamed surface with an antiseptic solution and a spray, the entire inflamed surface was covered with a mild zinc and bismuth salve on absorbent lint, and the arm put on a perforated splint. After the third day the inflamed parts were in a more healthy condition, granulating freely, and, after several more days, in order to facilitate the healing process, I concluded to use skin grafts, if possible from the patient

himself. Accordingly, and with the kind assistance of Dr. E. Clavin, of this city, we removed from the upper thigh of the patient a number of good-sized skin grafts and applied them, under proper precautions, according to Thiersch's method in Leipzig, and covered the surfaces with oiled silk, etc. After the second day of this procedure I prepared the photo, No. 1, seen in the BRIEF, showing the numerous grafts well adherent to the large granulating surface. Then, about ten days later, the next, photograph No. 2, was taken, showing the grafts nearly disintegrated, and transformed into cuticular and cicatricial tissue. After another ten to fifteen days, the photo, No. 3, was taken, showing the arm entirely healed, with good, sound skin.

725 East Commerce Street.

Biochemic Medicine—Salt or Muriate of Soda.

BY J. S. LEACHMAN, M. D.,
Higley, Oklahoma.

I note in the December issue of the MEDICAL BRIEF, page 897, an article by Dr. L. S. White, headed "Should We Eat Salt?" I will begin by saying that salt or muriate of soda is one of the cell salts of the blood, and is just as essential as iron or any other cell salt of the blood. To see a person eating salt shows conclusively that salt is demanded in the system, that there is a deficiency of this cell salt in the blood, and a homeopathic, or one well up in the biochemic treatment of disease, would give natrum muriate (salt) 3X in two and one-half to five grains, three or four times a day, and in a short time the patient would quit his salt eating.

In giving the salt in this way the cells of the blood can take it up, but in the ordinary table or barrel salt it is too coarse or dense for the cells to feast on. Muriate of soda, 3X, can be secured at any homeopathic pharmacy.

It does seem so strange that so many physicians know so little about biochemistry (chemistry of life). The blood supplies the material necessary for forming every fluid and tissue in the body, and for carrying on every process. The body contains both organic and inorganic matter. The organic substances are sugar fats and albuminous matter; the inorganic constituents are water and certain minerals called cell salts. The cell salts are the vital portion of the body—the workers, the builders.

There are twelve salts and should a deficiency occur in any of these workers some abnormal condition (disease) arises. For the benefit of the readers I will name the inorganic cell salts: Flourine of lime, phosphate of lime, sulphate of lime, phosphate of iron, muriate of potash, phosphate of potash, sulphate of potash, phosphate of magnesia, muriate of soda (salt), phosphate of soda, sulphate of soda, silicea.

Here are the twelve cell salts. When a person is receiving a sufficient supply of the proper food and all the cell salts are at par, the workings of the body go on in a good, healthy manner, but from some cause or other, let there become a loss of any of these cell salts and the working of the body is deranged, and the proper thing to do would be to supply the deficiency. There are certain symptoms obtained by long clinical experience by such persons as Dr. William H. Schuessler, of Oldenburge, Germany; Dr. Walker, of Scotland; Dr. O'Connor and others, of America, that points out the cell salt or cell salts that are deficient. I have been using the twelve cell salts over twenty years. I would not want to practice medicine without them. In my bookcase can be found Dewey, Cary, Chapman, and Schuessler. All on the tissue remedies.

I think the reason that we find so many doctors so ignorant on the cell salts of the blood is because the biochemic treatment of disease was cradled or first taken up by a homeopathic physician. We find some physicians so prejudiced against any other sect or school of medicine but their own that you could not induce them to read anything outside of their own school. It is truly a pity we have men so narrow-minded in the profession. However, this is fast giving way, owing to independent medical magazines like the MEDICAL BRIEF.

I trust this will throw some light on the salt question.

[Written for the MEDICAL BRIEF.]

A Cure for Hydrophobia.

BY ELI G. JONES, M. D.,
New Brunswick, N. J.

The first thing to do when a person has been bitten by a mad-dog is to cauterize the wound with caustic potash, then apply a slippery elm poultice, to get up a free discharge from the wound. Give the patient two improved compound cathartic pills at one dose, to get a free movement of the bowels, also give internally tincture echinacea, ten drops, once in three hours. Give the patient a hot vapor bath. If the above treatment is faithfully carried out it will prevent hydrophobia in most any case.

Personally I have had several cases in my own practice, where persons had been bitten by a mad-dog, and the above treatment was used, and though the cases were watched for several years afterwards, yet there never were any symptoms of hydrophobia.

Symptoms.—After a time, from six weeks to eighteen months (called the period of incubation), the patient bitten will experience pain or an uneasy sensation in the spot where he was bitten, if the wound has healed up, the cicatrix tingles, aches, feels numb, cold and stiff, sometimes looks red and swollen. It may open and discharge a peculiar ichor, the pain extends to the central parts of the body, all this is a warning of the coming attack of hydrophobia. In a few hours the constitutional symptoms develop, he is excited and irritable, speaks of pain and stiffness about the neck and throat, he unexpectedly finds himself unable to swallow liquids; every attempt brings on a paroxysm of choking and sobbing, very distressing to witness. This may last two or three days, until the patient dies.

Treatment.—Because certain authors have called this disease incurable, shall we fold our hands and do nothing. Certainly not, it is our duty to try and cure the patient. I want to give to the profession a method of treatment that has proved successful in my hands. I have been called to cases where the most powerful narcotics have been given, yet the spasms continued. I first cauterized the wound with a stick of caustic potash, then applied a hot poultice of equal parts of pulverized lobelia seed and slippery elm; change poultice every hour, encourage free discharge from the wound. If the patient can not swallow any liquids, then give per rectum the following injection:

℞ Tinct. Capsicum.....1 pint.
Tinct. Myrrh.....1 pint.
Tinct. Ladies' Slipper.....1 pint.
Pulv. Lobelia Seed.....4 ounces.
M. Sig.: Shake well.

The above is called "The Compound Tincture of Lobelia," the most powerful anti-spasmodic known in the world. Use a syringe and inject two ounces of this liquid into the rectum, place a napkin against the anus to prevent the liquid escaping. It is well to add about a pint of warm water to the medicine. Wait an hour; if spasms are no better use four ounces of the medicine in the injection. In another hour, if the spasms are not so hard and not so often, give half the quantity of the medicine, viz., two ounces. Follow up this treatment every hour until you get full and free vomiting, then you may be satisfied that you have conquered the disease. When your patient can swallow, drop the injections and give him one-half a fluid drachm of the compound tincture of lobelia in a little water, as often as needed to keep his system well relaxed, and hold off the spasms. The poultice, as ordered should be kept on the wound as long as any symptoms of the disease remains.

While the compound tincture of lobelia, as per formula, is a powerful anti-spasmodic, yet it is a safe medicine to give in such cases. As I have used lobelia in all its different preparations, and in every case where it is indicated I pronounce it one of the best remedies in any *materia medica*, and as I have used it continuously since 1869, my opinion should have some weight. If you are called to a case in the stage where the patient can not swallow any liquids at all, give him about the same thing in pill form:

℞ Lobelin (Con.).....10 grains.
Cyripedin (Con.).....20 grains.
Capsicum.....5 grains.
Ext. Gentian.....q. s.
M. Ft. pills No. 20. Sig.: One to two pills should be given every hour until the spasms are under control and the patient vomits freely.

Every doctor in general practice should keep the above liquid and pills on hand in case he has a case of hydrophobia.

I have given the above cure to the profession because I feel it my duty to try to help my brother physicians to cure a disease whose very name strikes terror to the heart of the common people.

[Written for the MEDICAL BRIEF.]

Introduction to Dr. Mount Bleyers, Article "Reflections on Rejuvenescence."

Who in this life of ours has not indulged in reflections on rejuvenescence. The thought of approaching age, at times, fills us with alarm and regret, and the apparent decay of happy existences is wrapped in mystery for all, philosopher, poet, scientist and layman alike. We all long for some marvelous spring, whose crystal accents would murmur of perpetual summer and blue skies, but, as Dr. J. Mount Bleyer, in his essay, so eloquently points out, nature is the only fountain of youth that is watering this earth and giving strength and rejuvenance to all life.

The earth is but a gigantic workshop, wherein holidays are unknown. Observe the flower at our feet. What is it? Color, perfume, beauty of form if you like, but does it not also represent labor, the production of a little black seed that will, in turn, proclaim the vernal beauty of another year? And now search the vast horizon! All you see is breathing hard, full of activity and haste, astir with the fecundity of the earth. The leaves expand, the flowers are in a hurry, the corn grows without pausing; all the plants, all the herbs are competing as to which shall spring up quickest, and the running water, the mountain stream and meadow brook come to assist in the acts of regeneration, while the sun rising in the heaven is entrusted with the special duty of enlivening the common task.

And it is the same in human life. As the silence of winter will again produce the gayety of spring, a powerful summer and a bountiful autumn, age will change again into childhood, youth and maturity. Old age is but the peacefulness of twilight, the farewell of the sun, which dies at night to be born again in the morning. Therefore, let us courageously perform our task of life. The more we study the secret workings of nature the sooner will we realize, with a feeling of serene consolation, the great simplicity of death, which is merely a returning to spring, where our own lives transformed into new existences will commence the everlasting joys and sorrows of mankind over again.

SADAKICHI HARTMANN.

Reflections on Rejuvenescence.

BY DR. J. MOUNT BLEYER, F. R. A. M. S., LL. D.,
New York City.

Many learned men have spoken and written on the subject which this title bears, and the last words will never be heard or written on rejuvenescense. The word, rejuvenescense, literally speaking, means return to a state of youth. The most glorious principle of nature, impressed upon its every object, life and death themselves are only other names for rejuvenescense. The history of the world and of its contents in all their variety and phases, is no more than the history of its operation; the one great poetic idea of the universe, all phenomena and splendors, spiritual, as well as material, are but parts and elements of it, illustrating and adorning its different modes. Everywhere, since the first morning, has youth been incessantly bursting forth, and creation beginning afresh. "The universe, open to the eye to-day, looks as it did a thousand years ago; the morning hymn of Milton does but tell the beauty with which our own familiar sun dressed the earliest fields and gardens of the world;" all things, says the Apostle, "continue as they were from the beginning of creation." True, there is continual dismemberment and disintegration; the flower fades, the animal falls to dust, but this is not death, it is merely the casting away of wornout vestures, in order that new may be put on. The form, the idea, the actuality, lives forever; the end always reverts to the beginning; from the plant comes the fruit, and from the fruit comes the seed, which again contains the plant within itself. Look at the sculptured pineapple! Nature in miniature; upon its yellow ripeness ensues a beautiful tufted crown of leaves, promising and beginning the whole history over again, the

true phœnix of creation.* The fabled palm is only a metaphor of the world. Turn which way we will we find no "killing principle" in nature, only a vitalizing and sustaining one. Throughout its whole extent, nature is life; in all its forms and modifications, one vast and infinite life; subject, no doubt, to the extinction of particular presentations, but never to absolute and total death, even in its least and weakest things. Anything that looks like death is a token and certificate of life being about to start anew and invigorated. Every end is also a beginning; all things in the world are striving to begin, as well as to finish; marriage once more is the type and exponent. So far from being the destroyer of life, death, rightly viewed, is its nourisher and aliment. A thing does not perish in order that it may no longer exist, but that another of the same or similar kind may enter fresh and beautiful upon the scene, and thus virtually perpetuate the original. "All death in nature is life and in death appears visibly the advancement of life. It is not death which kills, but the higher life which, concealed behind the other, begins to develop itself. Death and birth are but the struggle of life with itself to attain a higher form."† Granted, we do not perceive it to be so if we look at things merely with the outward senses; we perceive it in the degree that our own minds are alive, and apt, from culture and sincere and fervent aspiration after truth, to rejuvenize in themselves. Every thing is alive to the living mind. Death is abundant in proportion as the mind is dead. To estimate our intellectual vitality, at any given time, we have but to ask ourselves, How much life are we conscious of? We speak, in ordinary converse, of youth and age as distinct epochs, and, as a matter of appearance, correctly so. It results, however, from this great law, that so far from being separate and successive, they are contemporaneous and concurrent. Youth does not cease, and age begin. Throughout life their phenomena run side by side, revolving each upon the other, age succeeding youth, youth succeeding age, in the most varied conditions of exchange, and often crowding into the same region. Everywhere in nature we see youth and senility intermingled, presenting themselves alternately, and all together irrespective and independent of annual birthdays. If decay attend upon age, so does it upon infancy; if youth is a beginning, so, too, is maturity. Life rising out of death was the great "mystery" which, in old-time symbolism delighted to represent under the thousand ingenious forms preserved in mythology and ancient poetry, as in the lovely fable of Cupid and Psyche. Nature was explored in her every realm of attestations to it, the results giving to religion new sanctity and illustration, to philosophy, new dignity and grace. Sleep was beautifully called "the minor mystery of death;" since the seeming suspension of life during the stillness of slumber is the pathway to restoration of its powers, and thus a prefigurement of what death is designed for. "Death like sleep," says the illustrious herder, "cools the fever of life;" gently interrupts its too uniform and long-continued movement; heals many wounds incurable before, and prepares the soul for a pleasurable awakening for the enjoyment of a new morning of youth. As in my dreams my thoughts fly back to youth; as in my dreams, being only half-fettered by the bodily organs, and more concentrated in myself, I feel more free and active; so then, revivifying dream of death, will smilingly bring back the youth of my life, the most energetic and pleasing moments of my existence."*

When, then, it is said that death takes things away, it is said wrongfully. It is done by life, the constant aim of which is to obtain a point of departure for renewed progress, pushing out of the way whatever may obstruct. See what curious and striking illustrations are furnished in the physiology of our own bodies. The teeth of the child drop from its little gums, that the teeth of manhood may take their place; the blood, by its tiny particles, supersedes itself as fast as it is formed; every molecule of muscle, and

*The same beautiful onward growth appears conspicuously in several of the new Holland Genera of Myrtaceae, as Melalenca, Metrosideros, Beaufortia, e c.; and a similar phenomena in the canes of the Larch, from the apex of which occasionally extends a leafy root.

† Fichte, Destination of Man, page 27.

*Outlines of a History of Philosophy by Man. Book V, Chapter 4.

bone and brain in an ephemera; our entire fabric is taken to pieces every second of our life, and rebuilt long before we leave it. The bodies of all other animals similarly rejuvenize during the period between birth and dissolution; some, in addition to the molecular renewal, having periodical and most curious replacements of entire organs. Birds renew their plumage, lizards and snakes their skin, the crab even replaces its stomach, forming a new one every year, and casting away the old. Plants also rejuvenize, exemplified in annual renewal of their leaves and flowers. In the higher kinds of vegetation the phenomena are at once so marked and intelligible, as to have called forth the first and, as yet, the only treatise expressly devoted to this magnificent science.*

As a phenomenon of physiological or organic life, rejuvenescence appears under two great general modes, namely, first, return by the individual, either as a whole or in its molecules, to an earlier condition of existence, securing thereby a point of departure for renewed progress; secondly, repetition in a new being, under the law of procreation by male and female, of the entire course of organic evolution. The first has for its object the completion of the form; the second has for its object the repetition of the form. Rejuvenescence, in order to completion, is exemplified in the growth of a child, leading it on to puberty and thence to manhood; that which has repetition for its end, appears in the phenomena of generation and birth. It follows that it is the power of rejuvenescence which mainly distinguishes organic bodies from unorganic, since in their latter form there is neither a graduated development of the individual, nor renewal by procreation; without rejuvenescence there can be no organic development, nor where organs are absent can rejuvenescence ever occur.

The distinction between the two kingdoms of organized beings themselves, as regards rejuvenescence, is that while in animals there is a perpetual dissolution and rebuilding of the entire substance, the devitalized atoms being ejected; plants never rejuvenize a part once completed, but provide for the stability and regularity of the vital processes by developing new parts. The stem once formed and consolidated never alters in the least; the leaves and the flowers when done with, are disengaged, and absolutely new ones are unfolded in their place.

Rejuvenescence in order to the completion of the form, has, accordingly, for its chief process in animals, the decay and renewal of the tissues; in plants, the unfolding of new organs. Both involve a variety of union and contributive activities, but most especially is this the case in the rejuvenescence of the animal, where the full effectuation of the molecular renewal requires and is secured by the grand supplementary process of sleep; in effect a periodical return of the animal to its antenatal state, beautifully corresponding with the resumption of that state in lactation, which is living over again the life of the womb on a higher plan.

During sleep, the inner formation processes by which the body is preserved act undisturbedly and concentratedly. Everyone knows how sweet is the restoration derived from one's pillow when in health; more wonderful, even yet, is that which the patient derives when sleep occurs at the crisis of severe disease. The nocturnal refreshment of the physical frame induces a similar restoration of the spiritual. Relaxed from the tension in which it is held towards the outer world while awake, during sleep the animal sinks into a condition comparable to that in which it lay before consciousness commenced; all images and shapes it is cognizant of by day either vanish or appear only as reflected pictures; unexcited from without, it "gathers itself up into new force, new comprehension of its purpose, much that crossed the waking thoughts, scattered and entangled, becoming thereby sifted and arranged." Hence it is that "our waking thoughts are often our truest and finest, and that dreams are sometimes eminent and wise; phenomena incompatible with the idea that we die down like grass into our organic roots at night, and are merely resuscitated, as from a winter, when we wake. Man is captured in sleep, not by death, but by

*The phenomena of rejuvenescence in Nature, especially in the life and development of plants. From the German of Dr. A. Brann, by Author Henfrey Ray Society's volume, 1853, one of the most important of modern contributions to the philosophy of botany.

his better nature; to-day runs in through a deeper day to become the parent of to-morrow, and he issues every morning, bright as the morning and of life size, from the peaceful womb of the cerebellum." The most remarkable illustration of the bearing of sleep upon rejuvenescence, is supplied, perhaps, in the chrysalis period of insect life. Here takes place that grand retreat and gathering in of vital power which enables the unsightly grub to expand into the lovely, completed and expressive form we call the butterfly; so exquisite a symbol of the spring, when winter, the grub and chrysalis era of the vegetable world, is emerged from the superseded. The analogy is important to consider, because of the common, but mistaken impression that the charming queen exuberance of the vernal season is no more than the work of the few days during which it appears. The beautiful display is in preparation all the winter, just as the butterfly is in preparation in the grub and chrysalis. Spring merely brings the concluding steps before our eyes, as the rupture of the chrysalis the painted wings of the perfect insect. Not a little of the spring begins in the previous autumn, and even in the previous summer. The rudiments of the future leaves of the alder may be found in August; the leaves and even the flower buds of the lilac; the catkins of the hazel make their appearance with the asters and golden-rod; in the bulbs of the hyacinth, the tulip and the crocus, long before they manifest the least sign of vegetation the future blossom may readily be discerned. Insect life, as a whole, is the most perfect example we possess of rejuvenescence, having for its aim the completion of the individual. The true idea of what is so improperly called the "metamorphosis" or "transformation" of insects is development into perfect state. It is no change of one creature into another. The caterpillar contains within itself the rudiments of the future butterfly in all its parts; it becomes the butterfly, not, as commonly supposed, by a monstrous and supernatural mutation, but simply by casting its skin, and unfolding parts previously concealed and immature, first the limbs, by and by the wings, opening more and more, till the idea of the perfect insect is attained. No less striking and beautiful than the analogy of the butterfly with the opening leaves and flowers of spring, is the rejuvenescence, at that season, of the birds. They blossom in the spring like the trees and plants, glossy and tinted in their plumage, and, like the plants again, when they shed their petals, they lose their peculiar spring and summer luster immediately the process of hatching is completed.

To return, however, to the butterfly. In the insect's history we have a lesson of another kind. From time immemorial the butterfly has been the emblem of the resurrection. Anciently, as with the Egyptians, we find it drawn either in its prayer form or as a lovely female child with butterfly's wings. "Employed, subsequently by the Father of the Church, the beautiful symbol shone on their ponderous pages like a beam of sunlight falling through a painted window on the gloom of a cloister." The beauty and truthfulness of the emblem lie, however, in exactly the opposite direction to that ordinarily supposed. Not only is the usual idea of the resurrection, or that of a decayed body being recomposed and reunited after a certain interval to the soul, not represented in the natural history of the insect, but it is altogether contrary to it. What the history does teach is that which is also the true idea of the resurrection. Reaumur, that great and good naturalist, when he discovered the real structure of the caterpillar, and pointed out the discrepancy between the truth of nature and the dogma of the preachers, was denounced as an enemy to revelation.

Occasionally, but rarely, there is a man, a resumption, when old, of the external signs of youth. Cherished from the remotest ages, the idea of restoration of youthful health and strength and bodily shape, by some beautiful stroke of magic, is not altogether remote from fact, though the magic is in nature, rather than art, The basis, probably, of the story of Medea and Æson. It figures in the fables and national poetry of every period of the world. Its most beautiful embodiment, the Fountain of Rejuvenescence, is found in the tales of the Far East, in the romances of chivalry, and in the mysteries.

In the Middle ages it was the symbol of Christianity, renewing the moral strength of the world after the corruption of pagan Rome; and now we have it in a fine picture of one of the best of the French pre-Raphaelite schools.* The alchemists thought to secure such rejuvenescence by the aid of the philosopher's stone, which was not only to ward off sickness and infirmities, but replace men in the vigor of early youth. Vincent de Beauvais attempted to show that Noah's having children when five hundred years old was owing to his possession of this precious secret, whereby he had had restored to him the freshness of his ancient puberty. Modern scientists have sought the same trickster, though without a shadow of success. Vain expectation! Though man may certainly please himself with the reflection that he alone ever steps in the grateful path. The lower animals begin to decay almost immediately after the decline of their propagative power; in man, life is prolonged more or less after virility has ceased, and now and then operates over again some of the most characteristic phenomena of his earliest days.

The cutting of new teeth in old age, return of the power of growth of hair similar to that of the young, and several other such phenomena are abundantly on record, as may be seen at one view in Dr. Mehliss, whose curious work, "Weber Virilisczenz und Rejuvenescenz Thierischer Körper," Leipsic, 1838, has raised the matter into a branch of physiology. Of new dentition, for example, he cites not less than thirty or forty authentic instances, many of them octogenarian. For the appearance of these phenomena it is necessary, he tells us, that there should exist complete energy and integrity of vegetative life, and probably also local excitement.

The second great form of physiological rejuvenescence, or that by which man and all other living creatures, together with plants, renew themselves, as to race is expressed in the phenomena of procreation.

> Like leaves on trees the race of man is found.
> Now green in youth, now withering on the ground;
> So generations in their course decay,
> So flourish these, when those are passed away.

* M. Haussoniller "La Fountaine de Jouvenesce." See engraving in the Illustrated London News, September 13th, 1856.

Here it is that we most clearly understand that death, so called, is the operation of life. The particular aggregation of material elements, carbon, oxygen, nitrogen, and so forth, drawn together and consolidated by the immortal idea of each plant and animal, and by the spiritual body in man, break up and disappear after awhile, but in form remains with us still; its old apparel only parted with in order that new may be put on. Wonderful as are the processes of sustentation and repair in the individual, those of procreation, or the sustentation of the species, incomparably transcend them. No trifling work is the elaboration of a body which shall feed and grow, move and exchange offices of friendship; but to construct one which, in addition to all this, shall be able to engender new beings like itself, is the very acme of skill and miracle. So excellently has the subject been dealt with by other hands, so extensive also is its detail, that here I need only advert to it as one of the most solemn considerations of life, a subject never to be approached without reverence and awe. The unthinking part of mankind look upon procreation as no more than one of the common impulses of nature, and consider the slightest allusion to it improper. Many, even of those who ought to know better, regard it as ignoble and degrading, and its alluring incidents only as palliative and reconciliatory. There can not be a lower idea. In the whole range of delegated offices there is none more honorable and noble than to act for the Father of all, as perpetuator of the objects he has created "for his pleasure;" wherefore, also, the depth and fearfulness of its responsibility, since of all situations a man can place himself in, that of father is the most serious and manifold in duties. Large, indeed, should be the faith in heavenly succor of him who adventures upon progeny. The same is the ground of the brilliant delights which enter into its history, since outward circumstances is always made commensurate with the dignity of that which it accompanies and invests. The beauty which attends on the period when, with the complete evolution of the system, the power is attained of reproducing the species, is one of the most admirable phenomena of

nature. The principle is universally set forth. See how the plant, at its nuptial hour, adorns itself with bright flowers. See how the glow-worm trims its lamp, how the butterfly spreads its gallant pinions. In fishes and mammals puberty is again characterized universally by the development of ornaments more or less striking, such as brightly-colored scales and plumage, horns, manes and beards, the last named enhancing the manly beauty attained at this period in our own species, the female of which is even more largely embellished by the growth of the hair and the development of the mammal, and of the subcutaneous tissue of the body in general, giving to the limbs their matchless "lily roundness." Not only are beauty of form and color now most exquisite. Flowers smell their sweetest during the union of the sperm cell with the germ cell, especially in its central moments, losing their fragrance rapidly when it is completed. In the animal kingdom during the same period, sounds are emitted, pleasing, undoubtedly, to the ears they are designed for, and taking in man the form of poetry and music. The ballad, "To His Mistress' Eyebrows," of the lover, is the exact analogue of the grasshopper and cicada.* That the song of birds has immediate reference to their loves is generally understood. Like the beauty of their plumage, it rises to its highest during the pairing season, and is lost at the time of moulting. All our resident birds that renew their song in the autumn, probably have broods at that time. The thrush and the blackbird, which are heard from the middle of January to October, generally have two broods in the course of the season, and not infrequently three.

But it is not merely a pairing cry, being continued until the young birds break the shell, and, in many cases, until they are able to fly. Probably it produces general excitement in the female bird, while sitting, so as to increase the needful warmth, and a power of more energetic performance by both parents of the various duties of the nest. We all know that there are sounds, especially from those we love, which make the heart beat, and the bosom thrill, and the whole body glow, inspiring us magically and beautifully, and, doubtless, it is the same with the feathered dwellers in the trees.

Holding this sublime power of self-renewal as a part of its very nature, every animal, bird and insect, every tree and herb, down to the humblest moss, is in its procreant capacity an emblem and prefigurement of eternity. Forever rallying onwards, the truest and grandest idea of the Divine Life is unfolded to us in the phenomena of reproduction. Hence that beautiful custom of the ancients of placing seeds in the hands of the dead, and in their tombs and sarcophagi. They perceived that the renovation of a plant, by its seeds, year by year, and from age to age, unchanged in the least of its essential character, is a picture, in little, of immortality. The rites of religion always have reference to the theory; wherever religion has existed, the offices of the living to the dead have invariably formed a part of them, and, as all religious rites are of necessity symbolical, their beauty and intelligibleness show the quality of the faith which employs them. The custom alluded to thus testifies in itself to the antiquity of man's persuasion that he is to live forever.* With mankind, elevation to capacity for the privileges and rewards of procreation, is the effulgent aurora of existence.

Youth begins over again on a higher and more beautiful plan, whatever talents there may be in the soul, now they make their appearance. Early or late, whenever it may be first felt, love, the high priest of procreation, always leads the way to rejuvenescence of our entire nature. No pleasures are so sincere and so enduring as those which come late in life through renewal of one's youth under the sweet agency of a happily-placed affection, nor are any so thankfully enjoyed.

Let me pass on to the renewals that pertain to the spiritual degree of life. In the changes of our feelings we have rejuvenescences quite as beautiful as those of nature. The decay and retrogression which in autumn we see among the plants,

* Abridged, in part Dr. Laycock. British and Foreign Medico-Chirurgical Review, July 1855.

* The early Christians also put seeds in the coffins of the dead, but in their case it was in acknowledgment of the imagery of St. Paul. See an interesting article on the subject in Hooker's Companion to the Botanical Magazine, Vol. 2, p. 298.

providing the means of a charming pallingenesis in the spring, is not more regular and universal than are the declensions we are subject to in ourselves; nor does nature rebound more freely and improved. Whenever there is a return of the heart from unsatisfying, selfish, or ignoble pursuits, to a taste for the pure and uncloying charms of virtue and nature, there we have the restoration of our youth. Wherever there is advance into new and delicious fields of thought and feeling, under the influence of new scenes, or the advent of new friends, or the passing away of what is painful or distasteful, life starts anew in all its plenitude of powers and sentiment. How charming does Disraeli describe the rejuvenescence in old age, of well-cultivated literary taste!* "The steps of time are retraced, and we resume the possessions we seemed to have lost, we open the poets who made us enthusiasts, and the philosophers who taught us to think, with a new source of feeling acquired by our own experience." Adam Smith confessed his satisfaction at this pleasure to Dugald Stewart, while reperusing with the enthusiasm of a student the tragic poets of ancient Greece. The calm, philosophic Hume found death only could interrupt the keen pleasure he was again receiving from Lucian. "Happily," said this philosopher, "on retiring from the world I found my taste for reading return with even greater avidity." Lord Woodhous found the composing anew of his "Lectures on History" so fascinating in the last period of his life, that it rewarded him, Alison informs us, with "that peculiar delight which has been often observed in the later years of literary men —the delight of returning to the studies of their youth, and of feeling under the snows of age the cheerful memories of their spring." In the solitude and night of human life is discovered the unregarded kindness of nature, which has given flowers that only open in the evening, and bloom through the night season.† As morning and sunshine came back in the Hesperis, the evening primrose, and the night-flowering cereus, so do fancy and imagination rejuvenize.

There is abundant illustration of this great law, also in civil, scientific and literary history, especially the last, and it is worthy of observation that the precursor of a new era is always one who refuses to follow the slavishness, extravagances and caprices of exhausted invention, and returns to the freedom, simplicity and integrity of nature. This is why men of true genius, who illumine the world with something new and glorious, are always accused of violating the rules, *i. e.*, refusing to dwell among the tombs. What shallow-minded bigots call "heresy" and "heterodoxy" is often nothing more than the rejuvenescence of a devout and healthy soul, too far elevated above themselves even to care for their censure or wrath.

The great Syndenham, with whom the science of medicine rejuvenized, as it did with Harvey and Hunter, was conspired against to expel him from his college as "guilty of medical heresy." Death, in its blindness, always thinks that its contrary, or life, is the dead condition, as evil always pities the good, and would fain persuade us that itself is the *summum bonum*. When another kind of rejuvenescence was spreading under the genius of Lord Bacon, Sir Thomas Bodley wrote to him remonstrating on his "new mode of philosophizing." New doctrines always displease the small and stagnant souled, who may be known by their having nailed themselves to given opinions, and considering novelties vicious and illegal. Given to fancying that the world has been losing wisdom, instead of gaining it, since the period when they contracted their views, they must work by precedent or not at all, and hence are never anything but mimics. Not so the men of life and power. "The great men never know how or why they do things. They have no rules, can not comprehend the nature of rules. The moment any man begins to talk about rules, in whatever art, you may know him for a second-rate man; and if he talk much about them he is a third-

*"The Literary Character," Chap. XX. See also an original and beautiful "Account of the State of the Body and Mind in Old Age," in the Medical Inquiries and Observations of that most interesting writer, Dr. Rush. Vol. 2. Philadelphia, 1793.

†The number and variety of the flowers which expand or only become fragrant towards evening, show how deeply seated is this beautiful correspondence. Besides the familiar species mentioned, there are the Marvel of Peru, the tuberose, several species of the Geraniaceæ, as Pelargonimo triste; several of the Caryophyllaceæ, as Silene noctiflora and vespertina, and Dianthus pomeridionus; many tropical Convolvulaceæ, etc.

rate," as Goethe said, all great men produce their works as women do pretty children—without either thinking about it or knowing how it is done. All great epochs are epochs of resurrection. Not one of our modern institutions is purely an establishment of to-day. That which is, has already been, only under another and cruder form. The mode may be different, but the principle is the same. The truths we delight in as our own were pleasures to our forefathers; if we do recognize them in our readings in history it is because the ages in their spiral rise have lifted them to a higher level, as a building becomes different when we are close beside it from what it appears while in the distance. Ideas never die. Out of fashion for awhile; lost, perhaps, for generations, they bide their time, then revive, as Ovid says, "*In nova corpora mutata*," "changed into new bodies." No fragment of truth has ever been really lost. Immortal as its origin, every particle is sure to rise again, its resurrection the result of its immortality. All the great "revivals" of the present age partake of this character, and result from this mighty law. Let us be careful, then, how we ridicule even the least of them. Resuscitations can only happen where there is life; the absurdity may prove to be in ourselves rather than in the things. What the many are, such is the individual. The parallel between the soul of man and that of society is exact. "Every man," says Sir Thomas Browne, "is not only himself; there have been many Diogenes and many Timons, though but few of the name. Men are lived over again, the world is now as it was in years past; there was none then, but there has been one since that parallels him, and is, as it were, his revived self." We often cast our eyes towards the future. If we would speculate on it rightly, we must first comprehend the present, and that is best done by contemplating the past. True, in our retrospect we seem to see little more than destruction, but in the eyes of the naturalist this indicates renewal, transition into a new, up-growing time. Not a few of our greatest riddles have their solutions in ancient history, yea, even the fables of mythology; for mythology is not, as foolish people fancy, profane romance and nothing more, but sound and living prophecy, a sort of secular inspiration, suited to the times to which it was given, and intended to receive fulfillment in later days. We talk of the golden age as gone. Not so; the golden age is both with us and to come.

The highest rejuvenescence of all is man's return to youth in heaven. Some people think, weakly, that "death is the only reality in life; happier are those who see and feel that life is the true reality in death." Why then, call it death? And why mourn and weep for those who return to the springtime of existence? Why complain that we ourselves seem to be so soon taken from this land of tombs and replaced in the golden country of our pristine hopes and imaginings?

[Written for the MEDICAL BRIEF.]

A Fad of the Fakirs.

BY B. B. USSHER, M. D.,
Dedham, Mass.

The anguish of humanity has expressed itself more frequently over the loved one affected by tuberculosis, commonly known as consumption, to a greater degree than over any other disease. The agonized father has seen the loved child, just grown into manhood or womanhood, seized in the relentless grip of this disease, and neither prayers nor prescriptions have sufficed to restrain the taking off of the victim. Into every phase of home life this monster evil has stalked and taken whom it would, and at the bottom of it all was the foundation of heredity on which, with dead certainty, it waited for the superstructure of tuberculosis to be meted.

That fad known as the open-air treatment is simply on the basis of cure for consumption, a first-class delusion. In most cases coming under such treatment the patient has, for various reasons, chiefly poverty, been improperly fed and pestilentially housed. I have cases in mind now of persons who went to such a consumption-cure establishment. They were working people, women who were spending their lives indoors in sunless houses and damp basements. They were scantily fed, and that on unwholesome

food snatched as it could be got, and badly prepared. Spare of body, they were fairly bloodless, and in this condition of nervous exhaustion and physical debility, exposure brought to the front consumption, the visit to the sanitarium confirmed the idea that the lungs were tuberculous, and the poor scrofulous invalid was taken in to be done for. Air, rest and food were the three remedies, each and all of which she had been deprived of before going. But, presto, a dozen raw eggs a day, beefsteak that would fatten a lath, air that was as champagne without a vintage, rest unbroken as a child's sleep in its cot, cheerful company, and all the hygienic effects that increase vigor, and fat, rosy and seemingly healthy, with a smile where there used to be a hopeless frown, this seemingly metamorphosed individual is discharged, "cured." Cases of debility have been known to have come back well and strong and under the new treatment these have fairly held their own and kept strong under a new regime, but in these cases there was no tubercle present, there had never been, they were convenient for advertising purposes, but in the cases where there were really consumption established those interested were not informed that when the old life was resumed with its hard work, bad air and poor food, the flesh vanished and the tubercular symptoms resumed sway, and the galley slave of poverty and privation went to the grave at a quick march, clad in all the physical livery that that despot, tuberculosis, compelled them to wear.

The microbe theory has run mad as a factor in diagnosis, and the owlest amongst the would-be scientifics gave us, who can not live with a microscope to our eye, a lot of solemn bosh when they tack it on to the affliction known as consumption. The way to cure consumption is to commence with the parents of the unborn and teach them how to raise strong, healthy children, even in poor environment, and none other should be raised. Not until we kill out the absurdity of breeding children of parents that, were they cattle, we would not dream of reproducing their worthlessness, will we stamp out a disease that is simply an effect from an hereditary cause. It is amusing, were it not saddening, to hear of physicians telling patients that they have examined their blood and sputum and both were full of "bugs," and after awhile, under a religious following out of their treatment, they declare, "not a bug to be seen," but the poor patient, in spite of the exodus of "bugs," still feels badly and, finally, succumbs, but, of course, it was not tuberculosis that was cured. Alas for the deceived ones, they do not feel any better for the use of a new nomenclature, with a wise look they only know the best they could do was done.

Vaccination.

BY J. CRESSWELL LEWIS, A. M., M. D.,
Benicia, California.

Much is being written *pro et contra* on the subject of vaccination, champions and foes of the practice being equally alert to make the theme look well from their respective standpoints.

There is no doubt that since vaccination has been so extensively practiced, variola has not been so prevalent. Of course, sanitation and isolation of patients have had a great influence in preventing the occurrence of epidemics; and we must remember, too, that diseases run in cycles, appear and disappear, run rampant for a time, and then leave the stage of action, and go to the mysterious sphere of the unknown.

As to the ultimate cause of diseases, as well as to their prevention, medical science is in doubt and ignorance, notwithstanding the great array of literature on these topics, which, with its prolixity and controversial character, perplexes and confuses the reader.

The purpose of the present paper is not to denounce vaccination, for the writer is studying the subject from the point of view of an unbiased observer, and has not arrived at the position where he would absolutely reject it; although, if there were not good reasons to believe that much carelessness has been exercised in the cases observed by him where bad results followed, he would surely be in active opposition to it.

He is not willing, either, to admit that there is no good substitute for vaccination. Men of undoubted ability and unquestioned integrity, claim to prevent small-pox by administering drugs, although the testimony is not yet sufficient to warrant him in discontinuing the practice.

The knowledge that, in his early practice, many were seemingly protected from variola by vaccination at his hands, and through the efforts of his father, has held him until now in the ranks of those who perform vaccination.

To be sure, in those days, humanized virus was used, and virus that we could depend upon, being taken from primary vaccinations of infants three months of age, whose family history on both sides was well known to us, the original stock being taken from the cow, many years before.

The general opinion now is that bovine virus is preferable, and the younger practitioners know nothing else, but with the same care used now as formerly the results have not been as satisfactory to the writer since the bovine virus has been exclusively used.

Passing over the many phases of the subject, which are interesting as well as important, we will confine ourselves to the consideration of the proper methods of performing vaccination and the after treatment.

Vaccination is not as popular among the people as it was forty years ago, as is evidenced by the compulsory laws that have been passed in later years. The great number of bad results that have followed it has caused such a commotion among the laity as to endanger the continued existence of the practice.

Some of these mishaps were unavoidable, we admit, and occurred in the hands of eminently successful and careful vaccinators, but many of them were the results of gross carelessness or ignorance, either of which is reprehensible.

It should be unnecessary to make any allusion to the simple operation of vaccination, but in view of the untoward results many times following its performance, and the adverse attitude of a large portion of the community, as well as of a respectable minority of the medical profession towards it, we are convinced that we are not guilty of supererogation at this time.

If, in the state of uncertainty many find themselves, in spite of statistics in its favor and of laws making it compulsory, the greatest good is to be accomplished through it, there must be exceedingly great care taken in every vaccination performed by medical men.

The age most suitable for primary vaccination is three months, because then there are not the objections to it, as later on, when the child is teething, and also because many cases of variola occur in the first year of life.

When there is small-pox in the family, or when, as sometimes happens, the mother has the disease at the time of accouchement, the child should be vaccinated immediately after birth.

In such a case, if the stage of areola arrives before the disease breaks out, the child is considered to be protected.

The vaccination should be done only when the subject is in good health, except in case of epidemic, when the risk must be taken.

The child must be free from any acute disease or from any chronic ailment known to be inimical to the ordinary course of the vaccine vesicle, such as cutaneous diseases. Even a history of hereditary tendency to disease must be considered, and the child be under observation and treatment for a time, to place the system in the best possible condition.

All these things being duly considered, and the child being thought a fit subject for the procedure, it should be done at once.

The best preparation of the parts, from the experience of expert vaccinators, is to wash them well with soap and water.

The application of alcohol, as is often recommended, appears to modify the action of the vaccine virus, and often prevents a successful result.

The purity of the virus, a matter of grave importance to the subject of vaccination and the family, we can vouch for only in so far as to the general character for reliability that the maker of it possesses. This the writer is always careful to impress on those vaccinated by him, or their parents or guardians, in case they

are young children. This relieves him of responsibility in case untoward results follow careful work on his part. Being able to refer to the maker of the virus and the date when it was issued is of great value in case trouble arises, as it does more frequently than in years gone by.

All good vaccinators of thirty or forty years ago knew that lymph directly from the cow had a more violent effect than that which had been transmitted through the human subject, producing sometimes a vesicular or papular eruption, called by the Germans nachpocken. This, at times, produced urgent symptoms, endangering life.

There are different modes of vaccinating. The method most in vogue is for the physician firmly to grasp the left arm of the child with his left hand, and with the thumb lance (made thoroughly antiseptic), or with the ivory point, on which the lymph is placed by the manufacturer, scratch the arm without drawing blood, and then, moistening the lymph on the point, rub it in well.

The lymph is also furnished in hermetically-sealed tubes, and can be applied after the scarification is completed, instead of using the ivory point.

Some prefer to scrape the selected spot with the lance until it is denuded, when they apply the lymph as before.

Puncturing at an angle of forty-five degrees to the skin has been selected by some, who claim this to be effective in producing satisfactory results.

The slight bleeding ensuing does not prevent a take, they claim, as the valvular character of the puncture in which the lymph is placed insures its retention.

This the writer has never done, but he knows an insufficient scarification is sometimes the cause of failure.

An important step in the procedure is to keep the child under our eye until the arm has thoroughly dried. Many cases of failure can be attributed to carelessness in this respect, as the parent or nurse will often allow the arm to be rubbed and thus spoil our work.

Having dried completely, the arm should be protected by a shield of our own contriving, or what is better, one of the various sorts we can now procure at a nominal cost.

Some claim that four or five vesicles should be produced to insure protection. Such, in our experience of over thirty years, is unnecessary, and inflicts more pain and inconvenience than is warranted.

Sometimes, in spite of all our care, the arm does not take, and we must repeat the operation. We have been compelled, in some instances, to do so even three times before we have had success. Some we have vaccinated that would not take at all.

The patient should be seen after vaccination and watched during the progress of the case. On or about the third day after vaccination a small papule is observed, which by the fifth or sixth day becomes a well-defined vesicle, with an elevated edge and a cup-like depression.

By the eighth day this is perfectly developed, is pearl colored, and the elevated edges and depressed center have reached their acme, while surrounding it is the classic areola.

The child will frequently be feverish, restless, have nausea and diarrhea, and perhaps, induration and enlargement of the axillary glands.

By the fourteenth or fifteenth day a brown, hard crust is formed, which falls off from the twentieth to the twenty-fifth day, leaving a cicatrix that is characteristic, being foveated, depressed and sometimes radiating.

In some cases we have an eruption, appearing at about the tenth day, which may be either vesicular or papular. This is generally of short duration, but may be protracted and prove serious.

Having taken all the precautions possible, the practitioner can not be charged with carelessness if bad results follow vaccination. He has done his duty, has conformed with the laws that are on the statute book, and has been obedient to that higher law of public opinion that demands his service.

For, uncertain as he may be as to the efficacy of the practice, he is warranted in doing as he does, while thousands of his brother physicians believe firmly in it, and are strong enough, numerically, to control the public mind.

A few months ago a young lady was placed under the care of the writer, who has suffered terribly as a result of vac-

cination, a primary vaccination in fact, who thus illustrates, in her person, the disastrous effects that attend on it at times.

A few days after having been vaccinated by a physician in San Francisco, in March, 1906, she developed symptoms that were serious, and, as far as the writer can judge from her subsequent description, were those of septic poisoning.

For three weeks she was quite ill and yet was assured by her medical adviser that hers was an ordinary case and was pursuing a natural course.

When able to get around, she presented herself at the writer's office in San Francisco. This was before the earthquake and fire of last April, which made great changes in the personnel of the profession in that city. She was then weak and anemic, had a large, ugly sore on the arm that had been vaccinated, which eventually sloughed and left a deep, penetrating ulcer, which healed slowly.

The day of terrors, April 18th, came and swept away a large portion of San Francisco, one of the most beautiful and delightful places of abode on the globe. The writer drifted with the great mass of those who were burned out, to Oakland, and, in two months' time settled down in Benicia, the one-time capital of California. His patient had lost sight of him, but when she found where he was, communicated with him and eventually came to see him October 13, 1906.

Her left arm was much smaller than the right, the circumference over the biceps showing a difference of an inch and a half in favor of the right arm. She had pain and weakness in the left arm, tingling sensation in the same, wrist drop, pain in precordium, palpitation and attacks of syncope. Her condition was grave. Before the time of her vaccination she was in good health. She remained so as to be under the writer's care. She was given general and local galvanization in the morning and local faradization in the evening, together with remedies indicated from time to time.

Gradually, she improved under the treatment instituted, until, about December 1st, she was able to discontinue treatment.

This case is noted as one that illustrates the dangers attending vaccination, and whether the physician was careless or not, in his operation, the fact remains that the subject of it suffered as a result of it, and suffered further as a result of his negligence or ignorance in assuring her that hers was an ordinary and natural case, and neglecting to give the necessary treatment.

As such cases come under our notice, from time to time, it should stimulate us to study well every such case, in order that we may arrive at a definite opinion as to the proper status to be given the operation of vaccination.

If all would honestly and persistently investigate, instead of taking everything for granted, medicine would advance more rapidly and mankind would be proportionately blessed.

[Written for the MEDICAL BRIEF.]

Examination Questions Nebraska State Board of Health, May 29-31, 1906.

ANATOMY.

1. Briefly describe the animal cell and the reproductive cell.
2. Name contents of the mediastinum.
3. Describe the occipital bone, naming articulations.
4. Describe the pleural membranes, and name arteries and nerves.
5. Give origin and distribution of the fifth pair of cranial nerves.
6. Give origin and insertion of the flexor muscles of the thigh.
7. Give origin and distribution of the sciatic nerve.
8. Describe the orifices of the diaphragm, naming structures that pass through each.
9. Locate the arch of the aorta, and name its branches.
10. Describe the prostate gland.

PHYSIOLOGY.

1. Describe the red blood corpuscles as to (a) origin and fate; (b) form; (c) size; (d) number; (e) function.
2. What is understood by endocardiac pressure? State the causes of the pressure in the arteries, capillaries, and veins.
3. Give the accepted theory regarding the mechanism of the secretion of urine.
4. Give the successive steps in the digestion of a meal of roast beef and potatoes.
5. Describe the temporary and permanent teeth, and the usual age for the eruption of each.
6. Describe the normal sounds of the heart, and state how they are produced, and where they can be most distinctly heard.

7. Describe the bile and its uses. Give test for bile.

8. Name one property common to all blood leucocytes. Give some of their physiological uses.

9. Write briefly on internal secretions.

10. Discriminate between the corpus luteum of pregnancy and the corpus luteum of menstruation.

CHEMISTRY.

1. Define organic chemistry, atom, and element.

2. How modify cow's milk to approximate human milk?

3. Write an equation showing production of H. and laughing gas.

4. Give chemical tests for strychnine and arsenic.

5. Define fermentation and putrefaction.

6. Describe accurately Heller's test for albumen.

7. What reaction, normal or abnormal, may be produced by that test?

8. What average amount of solids in urine, and how estimated?

9. What are the common determinations in chemical examination of gastric juice?

10. What is the composition of proteids?

SURGERY.

1. Name the most common curvatures of the spine; give etiology, symptoms, treatment of lordosis.

2. Give etiology, symptoms and treatment of empyema; give diagnosis of empyema, hemothorax and bronchiectasis.

3. What is a ranula? Treatment,

4. Give differential diagnosis of the following conditions: Intussusception, floating kidney, stricture of pylorus, bubonocele, varicocele, and undescended testicle. Describe fully the technique of operation for varicocele.

6. How would you treat a lacerated and contused wound of the hand?

7. Etiology, symptoms, clinical history of carcinoma of breast. Describe in detail operation.

8. Give technique of amputation through middle third of the thigh.

9. What is the significance of pain in the abdominal region?

10. Describe in detail two of the most common varieties of clubfoot, and give surgical treatment of each.

OBSTETRICS AND GYNECOLOGY.

1. Describe the human embryo at the second, fifth, seventh and ninth months, giving size and weight.

2. Describe the symptoms, and give the management of an incomplete abortion.

3. Describe a case of phlegmasia alba dolens, giving diagnosis, time of occurrence, cause, termination, and treatment.

4. Differentiate ovarian cyst, ascites, and pregnancy at beginning of fifth month.

5. Describe a case of puerperal fever, giving cause, time of invasion, symptoms and course.

6. Name and describe fully the contents of the uterus at full term, before labor begins, detailing the presentation and position of the child most frequent, in an uncomplicated, healthy case.

7. Enumerate the symptoms which indicate the death of the child *in utero*, and state what course should be pursued in such a condition.

8. Describe in detail operation for repair of (a) lacerated cervix, (b) complete laceration of perineum.

9. Give in detail the anatomy and physiology of the pelvic floor.

10. Name the different varieties of metritis; give causes, possible sequelæ, and treatment.

PATHOLOGY.

1. What is pathology?

2. Describe embolism and thrombosis.

3. Define and describe phagocytosis.

4. What is a neoplasm? Give some examples.

5. Describe sarcoma, fibroma, lipoma, myxoma, osteoma, and glioma.

6. Describe a primary and a secondary anemia, and give examples.

7. Describe pernicious anemia, chlorosis, leukemia.

8. Describe phlebitis, varieties, common causes, and course.

9. Describe and differentiate between gastritis, ulceration of the stomach, and cancer of the stomach.

10. Differentiate between arthritis deformans and acute polyarthritis.

PRACTICE.

1. Give symptoms of myxœdema. Give treatment.

2. Name the acute infectious exanthemata, giving period of incubation and specific bacterium of each.

3. Give diagnosis and treatment of acute eczema of the face in an infant.

4. Describe in detail the most common method used in the examination of stomachic conditions. Give diagnostic value of absence or presence of acids and juices, and significance of conditions found present.

5. Describe diagnostic significance of hematuria. Give etiological factors. How would you differentiate whether the kidneys or bladder were affected?

6. Give differential diagnosis of interstitial and parenchymatous nephritis. Give pathology of both diseases.

7. Give diagnosis, prognosis, and treatment of chronic pulmonary emphysema.

8. Give causes, diagnosis, and treatment of chorea.

9. Explain the diagnostic significance of the "knee jerk."

10. Give the abnormal heart sounds, and the point of greatest intensity of each.

Book Notices.

CHRIST AMONG THE CATTLE. A Sermon Preached in The First Congregational Church, Portland, Oregon. By Frederic Rowland Marvin. Fourth Edition. Revised and Corrected. Troy, N. Y.: Pafraets Book Company.

Nothing can be said more wisely, nor expressively, in regard to this work than the expressions of John G. Whittier: "I have read the excellent sermon by Frederic R. Marvin, with hearty approval. The sooner we recognize the fact that the mercy of the All-Merciful extends to every creature endowed with life, the better will it be for us as men and Christians. I hope the sermon will have a wide circulation, and teach its readers that the dear Christ is 'among the cattle,' as well as among their owners." In contradistinction to this is Mr. Rickaby's "Moral Philosophy," a text-book used in many Roman Catholic educational institutions, but not indorsed by many Roman Catholic writers. Mr. Rickaby says, concerning the rights of animals: "But there is no shadow of evil resting on the practice of causing pain to brutes in sport, where the pain is not the sport itself, but the incidental concomitant of it. Much more in all that conduces to the sustenance of man may we give pain to brutes, as also in the pursuit of science. Nor are we bound to any anxious care to make this pain as little as may be. Brutes are *things* in our regard." This sermon is a grand one and should be liberally read by all classes.

THE TRAGEDY OF BADEN. By Cary H. Wilkinson. New York and Washington: The Neale Publishing Co.

This is a story where the pictures of life are graphically and truthfully drawn, and the characters delineated with more than ordinary skill. A subject of life pictures that are, no doubt, based on facts that infuse habits of caution to those who have the will power to resist in times of temptation. The author is a most delightful and truthful writer, and the words, thoughts and utterances touch the true emotions of pure and good minds. A story of a beautiful girl, an orphan, placed in an orphanage, gets into the clutches of a villainous saloon man, and is held captive two years, then rescued—a pure girl—by a drummer for a New England coffee house, who was doped and left for dead, when his resurrection by the medical students is shown to be weird, spectacular, and dramatic. It is fascinating from start to finish, and is the work of a well-known resident of Galveston, Tex. Send to the publishers for a copy.

DISEASES OF THE DIGESTIVE SYSTEM. Edited by Frank Billings, M. D., Professor of Medicine, University of Chicago, and Professor of Medicine and Dean of Faculty, Rush Medical College. An Authorized Translation from "Die Deutsche Klinik." Under the General Editorial Supervision of Julius L. Salinger, M. D. With Forty-five Illustrations in the Text. New York and London: D. Appleton & Company.

The absolute knowledge in regard to diseases of the digestive tract courts the attention of all physicians, because of the past theoretical knowledge on the subject. And any work that has a practical knowledge of the subject should be considered. This work has the expressions of the most eminent men of Europe, such as Rosenheim, Fleiner, Leo, Strauss, Reigel, Ewald, Boas, Hirschfeld, Oser, Minkowski, Stadelmann, Krauss, Neusser, Vierordt, Strasburger, Hoppe-Seyler, and Nothnagel. The subjects are treated very fully and at the same time in a concise and practical manner. The diagnosis of the various diseases is fully discussed, and the treatment, including the dietary, is satisfactorily full and complete.

SUPPLEMENTARY ESSAYS ON THE CAUSE AND PREVENTION OF DENTAL CARIES. By J. Sim Wallace, M. D., D. Sc., L. D. S., Hon. Dental Surgeon, West End Hospital for Nervous Diseases, and Assistant Dental Surgeon, National Dental Hospital, W. London, Eng.: Baillière, Tindall & Cox. Price, 75 cents.

The essays included in this volume appeared originally in the "Transactions of the Students' Society of the National Dental Hospital," the *Dental Record*, and the *British Dental Journal*, and are intended as a fitting supplement to the author's work on the "Cause and Prevention of Decay of Teeth," the price of which is (in America) $1.50. If you are interested in this subject it would be well to secure these volumes.

A COMPEND OF OPERATIVE GYNECOLOGY. Based on Lectures in the Course of Operative Gynecology on the Cadaver at the New York Post-Graduate Medical School and Hospital. Delivered by William Seaman Bainbridge, M. D., Adjunct Professor of Operative Gynecology on the Cadaver, New York Post-Graduate Medical School and Hospital; Consulting Gynecologist, St. Mary's Hospital, Jamaica, L. I.; Consulting Gynecologist to St. Andrew's Convalescent Hospital, New York, etc. Compiled, with Additional Notes, in Collaboration with Harold D. Meeker, M. D., Instructor in Operative Gynecology on the Cadaver, New York Post-Graduate Medical School and Hospital; Assistant, Department of Gynecology, Vanderbilt Clinic, College of Physicians and Surgeons, New York. New York: The Grafton Press, Publishers. Price, $1.00.

While this work is primarily intended for the post-graduate student, there is enough of good material for the general practitioner who desires to do abdominal surgery, and he will find in the chapter on "Miscellaneous Points" many suggestions of a practical nature. It is a book that can be recommended to the student and practitioner.

A COMPEND OF MATERIA MEDICA, THERAPEUTICS AND PRESCRIPTION WRITING. With Especial Reference to the Physiological Action of Drugs, Based on the Eighth Revision of the U. S. Pharmacopeia. Including also many Unofficial Remedies. By Samuel O. L. Potter, M. D., M. R. C. P., London. Seventh edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co. Price, $1.00.

This is one of Blakiston's Quiz Compends, a series of Quiz works that have stood the test of years and are now more popular than ever.

THE PRACTICAL MEDICINE SERIES. Comprising ten volumes on the Year's Progress in Medicine and Surgery. Under the general editorial charge of Gustavus P. Head, M. D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Vol. IV.—Gynecology. Edited by Emilius C. Dudley, A. M., M. D., Professor of Gynecology, Northwestern Medical School; Gynecologist to St. Luke's and Wesley Hospitals, Chicago, and C. von Bachellé, M. S., M. D., Gynecologist to the German Hospital, Chicago. Vol. V.—Obstetrics. Edited by Joseph B. De Lee, A. M., M. D., Professor of Obstetrics, Northwestern University Medical School. With the collaboration of D. Roehler, M. D., and Herbert M. Stone, M. D. Chicago: The Year Book Publishers. Price, $1.25 per volume.

Every student of medicine will find his work made lighter and more satisfactory by reading the volumes of this series in medicine, and he will get a good habit by frequently referring to them. They are of a size to be convenient and handy, and can be carried with him. Have you ever seen a copy? If not, get one and be convinced.

A TEXT-BOOK OF SANITARY AND APPLIED CHEMISTRY, or The Chemistry of Water, Air and Food. By E. H. S. Bailey, Ph. D., Professor of Chemistry, University of Kansas. New York: The Macmillan Company. Price, $1.40.

This book is primarily good for all students of chemistry and especially those who have only had a rudimentary high-school knowledge of the subject, yet it is also a text-book in its entirety, owing to the vast amount of information on its pages. It gives some simple rules, yet the full text is complete on the subject of chemistry, and will be an absolute guide on the subject. If you want to study chemistry from the foundation up to all its intricacies, secure this work and lay the foundation for success.

THE MEDICAL STUDENT'S MANUAL OF CHEMISTRY. By R. A. Witthaus, A. M., M. D., Professor of Chemistry, Physics, and Toxicology in Cornell University. Sixth Edition. New York: William Wood & Company. Price, $4.00.

Think of it, if you want a work on chemistry, that this is the sixth edition of a book that has stood the test for accuracy. Could you be induced to look further, when you are told that this work has been revised to date?

THE INFLUENCE OF THE MIND ON THE BODY. By Doctor Paul Dubois, Professor in the University of Berne, Author of "The Psychic Treatment of Nervous Diseases." Translated from the Fifth French Edition by L. B. Gallatin. New York and London: Funk & Wagnalls. Price, 50 cents.

Dr. Dubois has a well-earned reputation as a specialist in the treatment of nervous disorders through psychic suggestion, and whatever he writes upon the subject will be read with interest. It will do good to all who read this work.

Editorial.

National Taxes Too Great Already.

The message of President Roosevelt, at the opening of Congress last December, contained a greater number of radical recommendations than were ever bunched together in a presidential message before.

Some of them were decidedly revolutionary, and most of them were impractical and visionary, and yet they were delivered with as much *sang froid* as was his attempt, a short time previously, by imperial edict, to change the orthography of the language.

Among the many new measures which the President urged upon Congress was an inheritance and an income tax.

Now what the President wants to increase the tax burdens of the people at this time for, we are at a loss to know. In spite of the recent enormous increase in the Government's expenses, there will be a surplus in the Treasury at the end of the present fiscal year, according to Secretary of the Treasury Shaw, of $58,000,000.

This estimate is likely to prove too low rather than too high, as the Government receipts since the estimate was made clearly indicate.

The President does not specify the rate at which he wants incomes and inheritances taxed, and so it can not be known how much money he wants from these sources. However, the yield from the income tax alone in the last year of its existence in this country (1865-6) was $72,000,000.

Practically no part of this large amount was derived from the Southern States, and it was collected at a time when the resources of the country had been drained by four years of the most expensive war in history.

If an income tax, at the same rate as the last, were levied now, it would proba-

bly produce something like $1,000,000,000. There are no figures at hand upon which to base a calculation as to the probable amount an inheritance tax would yield, but it would amount to a huge sum.

But let us say that the two proposed taxes would, together, produce $1,000,000,000, and we do not think the estimate excessive. What use is there for all this money? There is a big surplus on hand under present taxes. Then why take more? Would it not have to be spent? And for what purpose? It would serve only as a temptation for extravagance and corruption, and, by withdrawing so much money from legitimate channels, it would almost certainly precipitate a panic.

There would be some excuse for the President to propose new tax measures if he had suggested a reduction in the internal revenue or the tariff taxes. But there is not a word in his message indicating any such desire. He wants more money and a lot of it, and that is all there is to it. Or was his purpose only to cater to the ne'er-do-wells by this threat to tax thrift and enterprise?

There never was a greater truth uttered than when Grover Cleveland said, "Unnecessary taxation is unjust taxation. Unjust taxation is robbery."

The Government has a right to demand from its citizens sufficient funds for an economical administration of the Government, but every cent which is taken beyond this amount is robbery. The people are already paying about eight hundred millions a year for the support of the National Government. Will they submit to still greater exactions? We do not think so.

"Shorts."

Short sheets, short blankets, short mattresses and short bedsteads are said to do more harm to hotels and railroads than all other causes combined. Doctors complain that at some hotels they can not make their patients comfortable. When they pull the covers over their shoulders it comes off their feet, and *vice versa*.

This state of affairs is probably harder on commercial travelers than any other class of men. It is getting so that only very short men can be commercial travelers. Hotels that treat their guests O. K. in this respect should advertise the fact, so that traveling people can know where to stop. Doctors should use their influence with hotel proprietors to have this nuisance stopped. This short nuisance is creeping in the underwear department.

Hand Railing.

Architects and builders should provide a hand-railing to all steps, whether in or out of doors, for the benefit of old people and invalids.

Physicians are now using their influence with architects to make some progress in this direction.

Suffering humanity is depending on doctors to get for them the ordinary comforts of life.

The Disadvantages of a German Education for the American Medical Practitioner.

The BRIEF has, on numerous occasions, pointed out the fact that it was time and money wasted for American physicians or students to go to Germany to complete their medical education. We are not sure that it is necessary to go to any foreign country for this purpose, but we have urged that if our physicians want to go abroad at all, they had better go to England, where the standard of the profession, and the advantages afforded are quite equal to those in Germany, to say nothing of the very important fact that it is almost out of the question for one who has not a thorough acquaintance with the German language and German methods of thought, to get very much benefit from attending German colleges or clinics. We are, therefore, glad to see other medical journals taking this view, and we print the following article on the subject from the *Interstate Medical Journal:*

So much has been written on the advantages of a German education for the American physician that he who would take a stand against the wave of enthusiasm must needs be a brave, not to say a foolish, man to stir up a hornet's nest.

Enthusiasm is not to be undervalued when it is the resultant of a thorough and wise interpretation of a human act or of another

spoke in the wheel of progress for the improvement of the human intellect, but when it is a mere bubble, kept on high by the vaporings of chuckle-headed individuals, it is time to prick it in the hope that by doing so the purblind may be brought to their senses, and the small voice of the few medical non-conformists may be heard.

The raw product that comes to our medical colleges makes strenuous efforts to over-educate itself in four years, and then, like any other superior person, flies to Europe for another addition to the indigesta that are a weariness to his mind and body. Needless to say, he returns with a smattering of German, such as *Das Mann* and *Der Frau*, and a complete knowledge of surgery, garnered in three or four months by gazing through magnificent distances at an operating table (the subject is never seen) over the heads of hundreds of other students, and a dozen or so assistants, who completely obstruct the view. Not only does his brief sojourn in Germany yield him little profit, but the many new and startling innovations outside the medical clinics, obfuscate his brain, so that commiseration, instead of blame, should be his due.

The German-American physician, on the other hand, is in a state of preparedness to profit by contact with new conditions. His knowledge of the language, his idealism more German than American, his point of view, which makes him appreciative and discriminative at once when on German soil, yield him advantages over the non-linguistic American too numerous to mention. But he who is handicapped by knowing but one language, and has merely read of Germany in books, whose very essence is garbled, can not expect an immediate adjustment of German conditions; in fact, a full month elapses before he feels himself orientated. As for the remaining three months which he wishes to devote to clinical observations, the lack of varied and complete cosmopolitanism makes him a mere "looker-on in Vienna," instead of a student profiting by working in the midst of things.

This is no disparagement of German medical knowledge, but a criticism of a large number of American physicians who, upon their return home, express great dissatisfaction with their work whilst in Germany, when the truth of the matter is that their minds, steeped in American thought and American social conditions, are not receptive enough to grasp, in a short space of time, the fruits of German medical science. For these men, and they are the element that shall make us proud of medical progress at home, the medical schools at Boston, Philadelphia and Baltimore at present are second to none, both for clinical material and laboratory investigation. By going there their education may, eventually, take upon itself that better phase, derided as culture, but so much better than over-education, which spells to-day nothing but a pinch of German, a little Latin and less Greek, with which to bamboozle the public.

Fads and fancies have always been our besetting sin, and no greater sin against advancement of true American medical knowledge has ever been committed in this country than the foolish attempts of wild-eyed enthusiasts of German universities to ruthlessly tear from the brow of American culture the few bay leaves we suffer her to wear.

Prevention of Chronic Suppuration of Middle-Ear.

BY H. H. LOOK, M. D.,

Instructor of Ophthalmology in the Medical Department of the University of Kansas; Ophthalmologist of the K. C. Southern Ry., St. Joseph's Hospital, Etc. Kansas City, Mo.

The number of chronic suppurative middle-ear diseases that have come under my observation in the last six months prompts me to write a brief article for the purpose of calling attention to this evil, and urging more careful consideration of the unfortunates afflicted with this disease.

By chronic suppurative disease, I mean a condition that has persisted in spite of treatment or through neglect for at least three months. Statistics of mortality in infants show that eighty per cent gave evidence of purulent inflammation of the middle ear. How often have we been called to the bedside of infants suffering with gastric disturbance, rise of temperature and restlessness and failed to discover the real cause until it is revealed by discharge or some complication.

Of acquired deafness, statistics show that twenty-five per cent are due to eruptive diseases, of which scarlatina and measles play an important role. This shows the necessity of inspecting the ears at each visit when treating these diseases.

The laity, generally, have the impression that a discharging ear is a trivial matter and will heal of itself, but this is true of only a limited number of cases, and it devolves upon the family physician to warn them of the danger.

The tympanic cavity is the seat of trouble in about seventy-five per cent of all ear diseases. Though it is deeply seated and, apparently, well protected, this cavity may become infected by way of the external canal, though eighty per cent of

middle-ear disease is due to the infection from the naso-pharynx, through the eustachian tube. Knowing that the naso-pharynx is constantly inhabited by pathogenic germs, and that it is the most frequent seat of trouble, any condition that may excite inflammation or have a tendency to prolong, must be removed. The removal of irregularities of the septum, spurs, enlarged turbinates, are of great importance. In one-sided nasal stenosis, the ear of the same side is usually affected. Faucial tonsils, when chronically enlarged, are an indirect cause of middle-ear disease, and should be removed.

Enlarged pharyngeal tonsils, or adenoids, when present, are a constant menace to the ear. Not only is the ear subjected to danger, but it produces malformation of the nose, throat and chest. Where these growths are large enough to interfere with normal ventilation and nutrition of the ear, or produce obstruction of the air passages, they must be removed. The danger to the middle ear is much greater when the naso-pharyngeal inflammation is due to some general disease, as scarlatina, measles, diphtheria, and especially influenza, than an inflammation purely localized in the throat and nose.

The external causes may be due to disease of the auricle and, as the external canal is also inhabited by pathogenic organisms, any injury caused by cleansing the canal with ear spoons, etc., may infect the middle ear.

Catching cold, no doubt, is an important factor in causing middle ear disease, though I do not believe that it will produce ear trouble without the co-existence of one or more of the above conditions.

Treatment.—It is my opinion that seventy-five per cent of the cases of chronic suppuration could be prevented by instituting proper and efficient measures in the acute forms. As the acute suppurative otitis frequently follows the non-suppurative variety, and as a differential diagnosis is difficult without a perforation of the tympanic membrane in the more severe forms of the non-suppurative, I will consider the two diseases as one, under the headings of the non-perforative and perforative varieties, regardless of the character of the fluid in the tympanic cavity, so as to conform with the general treatment outlined below.

Non-Perforative Variety.—Where there is a slight bulging of the drum, and if pain is not severe, our object is to bring about resolution of the exudate and avoid perforation. The treatment consists (having previously sprayed the nose and throat) in inflating the middle ear by means of the Politzer bag, for the purpose of removing the fluid in the middle ear, restoring the drum to its normal position and prevent adhesions by massage. If pain is present, a few drops of ten per cent carbolated glycerine instilled into the external canal will give relief; it is an antiseptic, anesthetic, etc. Heat is also used in various forms.

The general health should receive attention. If the symptoms do not improve under this treatment in two or three days, incision of the tympanic membrane is indicated.

Perforative.—Where there is marked bulging of the drum and intense pain, whether the fluid in the tympanic cavity be non-purulent or purulent, our object is to facilitate the discharge and prevent mastoid and intracranial complication by doing a paracentesis. We not only lessen the danger of chronic suppuration, but shorten the disease by one, two or three weeks, and hearing is restored to its normal condition. Free drainage and strict antiseptic precautions constitute the most salient factors in the successful treatment of acute ear disease.

After paracentesis, treatment consists of cleansing the canal by mopping it with cotton. Sterilized gauze is packed in the canal, and an external pad applied to the ear.

The discharge in acute troubles may be profuse, but in chronic suppurative otitis media it is scanty, very rarely profuse and may have an offensive odor. The degree of impairment of hearing depends largely upon the destruction brought about by the acute stage, from a slight impairment to a complete loss of hearing.

[Written for the MEDICAL BRIEF.]

Some Indications for Bleeding.

BY S. HERBERT PERRY, M. D., M. R. C. P.,
Assistant Physician to the General Hospital and Physician to the Out-Patients' Children's Hospital.
Birmingham, England.

Venesection, like leeching and cupping, have, during the past quarter of a century, passed somewhat out of fashion. In times gone by bleeding was apt to be employed inopportunely, to be misdirected, and to be pushed beyond its proper and safe limits; of late, medical practice has rushed to the other extreme.

Our lay friends never tire of telling us that medical opinion is a mere change of fashion, and we can hardly deny that we have, to some extent, laid ourselves open to this statement in the matter of venesection. For the custom of blood-letting has passed, during this century, through two stages, those of over use and of no use, and is now passing into a third, and, I hope, last stage, that of rational and moderate use.

Yet the question of the therapeutic value of venesection receives but scant notice at the hands of writers of text-books on medicine and therapeutics. It is one of the "debatable grounds" of medicine, and, for the most part, it appears to be thought best that the medical student should leave the matter alone. I can not agree with this attitude, since I hold that venesection, properly used, is a most valuable therapeutic agent. I have, in my own mind, almost a fear that in these days of scientific medicine there is a tendency to neglect the most obvious field that lies before us, that of clinical experience. Pathological and physiological theories rise and fade before us with a bewildering rapidity, resembling a show of fireworks. Clinical research is more concrete, and deals with facts rather than theories; and we must remember that however skilled a man may be in the laboratory, it is by his clinical knowledge that he must stand or fall in actual practice.

A word upon the method of venesection. The older surgeons appear to have advised the opening of a vein by one incision. This method has, to my mind, certain disadvantages. In making one direct incision into the vein one of two things may happen—the vein may be completely divided, or may be imperfectly incised, and, in the latter case, thrombosis will rapidly occur at the incised point, and another vein may need to be opened. This I have seen to happen on several occasions in inexperienced hands. My method is as follows: Make an oblique skin incision over the chosen vein, and then—turning the back of the scalpel to the vein—transfix it, thus making sure that it is semi-divided. A moderately tight turn of ban-

dage has, usually, been previously placed centrally, and the skin cleaned.

This method is certainly an improvement on what I may call the scratching method of opening a vein. Our professional forefathers, also, sometimes wounded the brachial artery, or caused a later arterio-venous aneurism by their bolder methods. Ethyl-chloride may be used to produce local anesthesia, but it is not usually advisable in the conditions which demand venesection.

There is a certain practical difficulty in advising a blood-letting. The patient is apt to regard the matter as an affair of much gravity, and his death will assuredly be laid at our door if it follow on closely. With the exit of the frequent blood-letting of years gone by, there has come a general shrinking at the sight of blood. Truly, indeed, one may say with one of the greatest of our romance writers, that our forefathers "took a braver heart to battle than we take—to the dentist."

I now proceed to the basis of my paper. I shall deal only with such indications as I have deduced from my own cases, and shall consider such indications under the heading of the diseases in which they occurred. These diseases are:

1. Acute pneumonia.
2. Cardiac disease.
3. Acute and chronic nephritis.
4. Cerebral hemorrhage.
5. Heat stroke.

It is to be clearly understood that this list is not put forward as a summary of the diseases in which venesection is of value, but is merely a list of those diseases in which I have seen it used with advantage, or otherwise.

Venesection in Acute Pneumonia.—I deal first with this disease because most of my venesections were performed in the course of it, and because I look upon pneumonia as essentially a disease in which life may be saved and distress much relieved by a timely blood-letting. Acute pneumonia is one of the few diseases in which venesection may be used as a curative agent; that is, as an agent that may directly aid in the restoration of normal health to a patient—and not merely as a palliative, as in chronic cardiac disease.

Looking through my series of cases, I find three types of acute pneumonia in which I consider that venesection was used with advantage to the patient.

1. In the early stages of cardiac failure.
2. In pneumonia, complicated by considerable acute bronchitis.
3. In plethoric pneumonia.

With these three types I will deal briefly in turn, taking first the cardiac failure type, as being the most important and including the larger number of cases.

1. In the early stages of cardiac failure.

We may take the following as a sufficient group of signs of cardiac failure in pneumonia:

(*a*) Signs of dilatation of the right ventricle.

(*b*) Increasing dyspnea.

(*c*) Commencing edema at the bases of the lungs.

(*d*) A secondary decrease in the loudness of the second sound in the pulmonary area.

(*e*) Certain alterations in the blood pressure.

The increasing dyspnea, mentioned above, has this point about it, that it becomes distressing to the patient, whereas I do not think that there is usually subjective distress in respiration in a favorable pneumonia case.

To sign (*d*) I am inclined to attach some importance. A secondary decrease of the pulmonary second sound is one of the earliest and most important of the signs of right ventricle failure. In the earlier and favorable stages of an acute pneumonia, the pulmonary second sound is typically accentuated, sharp and clear. Later on, a careful observer may note that the sound becomes dull and muffled, relatively, to its former tone. This change of tone may be associated with commencing resolution, with a decrease of dyspnea, and a general improvement. But, in my experience, the change of tone is most marked when it occurs with increasing dyspnea, growing lividity of the skin, and commencing pulmonary edema.

In the improving case, the alteration in tone coincide with the lowering of the blood pressure in the pulmonary area; in the graver case, the muffled tone of the second sound points to failure of the

heart muscle and dilatation of the right ventricle.

In several cases of cardiac failure in pneumonia I have observed this alteration in the tone of the pulmonary second sound to be one of the earliest—if not actually the earliest—of the signs of cardiac failure. If we allow the right ventricle to dilate to a marked extent, we have reached a most dangerous period. Venesection, to be of a real service, must be performed while the heart has yet a good potential vitality; it will be only a palliative agent if grave cardiac failure has occurred, more especially so if the failure occur early in the disease.

With regard to changes in blood pressure (*e*), I take the typically favorable pulse of acute pneumonia to be a full and fairly soft one. Pneumonia has a frequent, large, vehement pulse, with well-marked dicrotism.

In an unfavorable pneumonia, we may get some variety of pulse; I may mention two well-recognized forms. A failing heart may coincide with a high blood pressure, where the high blood pressure is probably a chief factor in the failure; or, where the heart muscle has weakened primarily from other causes, as excessive toxemia or high temperature, the pulse may be small and feeble. This feeble pulse may also be secondary to the evil effects produced by a high-pressure pulse.

The effect of a free venesection on the different types of pulse, above mentioned, will be obviously different. The high blood pressure pulse is lowered and softened, whereas the small and feeble pulse gains tone and becomes more full as the blood-letting relieves a heart and venous system distended and choked with blood.

2. In pneumonia and acute bronchitis.

I have seen excellent results to follow the practice of venesection in cases of pneumonia early complicated with much bronchitis; the profuse bronchitic expectoration being much relieved. All that has been said with regard to cardiac failure applies to this type also. I am inclined to think, however, that in this class of cases we should bleed early in the disease, in order to relieve the bronchitis, and that we need not wait for signs of cardiac failure, since if these appear they are necessarily of greater gravity than in an uncompleted pneumonia.

I need hardly point out that venesection must always be quite inadvisable in old or debilitated people.

3. In plethoric penumonia.

By the term plethoric pneumonia, I refer to a type of case familiar to all. The patient is a stout and, to the lay mind, a robust man, with high blood pressure, and is generally in much pain and distress. He is typically the subject of full feeding and of over full drinking. He is a bad subject for penumonia, and is, I believe, helped by a free venesection early in the disease, say to sixteen or twenty ounces. I am aware that the treatment may here be termed empirical, and a reversion to the ways of our forefathers. Yet it is better to relieve our patient as an Empiric than to fail as a Rationalist.

Doubtless, in other types of pneumonia, venesection may be indicated. I desire only to draw attention to the forms which I have had an opportunity of observing.

Venesection in Cardiac Disease.—In this matter my experiences are limited to chronic *morbus cordis*, and, speaking generally, I may say that I have not a good opinion of the use of venesection in this condition. When the cardiac muscle is degenerated or diseased, venesection can only be of value as a temporary remedy. The true value of venesection is here absent. I refer to the tiding of an organically healthy heart over an acute emergency, for in such a case lies the real value of blood-letting.

We have all seen a venesection save life, for the time being, where a sudden emergency, such as an unusual strain, has caused failure of degenerate heart muscle; but this blood-letting can do no permanent good. It might, however, and often would, relieve us from the gravity of a sudden and distressing death. The case I have in mind is within the knowledge of all. A patient, having chronic cardiac disease, is brought to us purple with cyanosis, the superficial veins standing out, the respiration much distressed. The exhibition of one of the nitrites will afford relief to such a case, but not so effectively as a blood-letting, for reasons which are obvious and mechanical. The nitrites, by dilating arteries and arteri-

oles, relieve a part only of the peripheral obstruction; they only relieve indirectly the venous system, and still more indirectly the capillary system. In these cases of heart failure we commonly find a choked venous and capillary system, a dilating heart, unable to contract and the peripheral arteries of small volume and ill-filled. By a timely venesection we lessen the the actual amount of blood flowing to the heart, and directly diminish the blood pressure in the local capillary area affected. The heart has, therefore, less blood to deal with, and a clearer path through which to drive it. In this manner an opportunity is afforded to the heart of recovering from temporary strain and of resuming its function. When we consider that the heart is an organ which has no rest, save its own diastole, we may in some way understand how great may be the relief afforded by the abstraction of twenty ounces of the blood in circulation.

To pass from this digression, I suggest that there is in chronic cardiac disease a certain danger of producing or hastening the occurrence of thrombosis by the use of venesection. I have notes of two cases in which thrombosis followed on venesection, at some interval.

Case 1.—Male, aged fifty-nine years; suffering from chronic bronchitis and a right ventricle, much hypertrophied and dilated. On admission he presented great cyanosis and dyspnea and a pulse small and compressible. Great relief was given by the taking of blood—twenty ounces—from the arm. He improved during the following weeks. Six weeks after admission, after a movement implying much greater exertion than usual, the patient fell back in bed with general convulsions, and a sudden and complete loss of consciousness. The heart was now acting strongly, the blood pressure was high and the arteries were markedly degenerated. Thinking that a cerebral hemorrhage was occurring, I bled the patient again at once to sixteen ounces. No relief followed and the patient died five hours after the onset. The *post-mortem* showed a thrombosis of the basilar artery.

Truly, we may learn from our mistakes. The *post-mortem* examinations showed plainly that the treatment was wrong, and, possibly, hastened the end. I do not suppose, however, that a fatal termination could, in any case, have been avoided.

Case 2.—Male, aged twenty-two years, suffering from chronic mitral disease. On admission, he showed cyanosis, dyspnea, and great abdominal pain. The pulse was small, rapid and irregular. Venesection was performed to fourteen ounces, with marked relief to the patient.

He improved for three or four days, and then developed some consolidation at the base of the right lung. A few days later, he was seized with increasing dyspnea and vertigo. On the following day complete right hemiplegia and aphasia were observed, and death followed shortly.

The *post-mortem* examination showed thrombosis of the basilar artery, as in Case 1.

In addition to the interest that lies in the fact that they were both cases of thrombosis of the basilar artery, these cases indicate that there may be a danger in using venesection in cases in which the heart and vessels are too far gone in disease to be able to accommodate themselves to the changes in the circulation brought about by the abstraction of blood.

In a case, for instance, of profuse hemoptysis, we may advise venesection, in order to produce thrombosis at the point of lesion. In a case of chronic cardiac disease, in which the blood is dammed backwards into the venous system, we shall usually tend to fill the systemic arteries by using venesection; but, if the heart be too far degenerated and dilated to react to such treatment, venesection may, possibly, tend to increase the chances of the occurrence of a peripheral thrombosis.

In Case 2, above quoted, the onset of the paralysis was typical enough of thrombosis; but in Case 1 the sudden onset, rapidly complete coma, and previous exertion, led me to diagnose a sudden hemorrhage.

I have notes of another case in which venesection gave temporary relief, but was of no permanent value. The case was one of general arterio-sclerosis, with a much-dilated heart, consecutive to lead poisoning and chronic nephritis. Venesection was tried for the relief of most distressing cardiac dyspnea, and suc-

ceeded so well that it was used on three occasions. Such treatment, however, could have no real curative value, and I should not be prepared to repeat it in a similar case, since the state of the heart and arteries necessarily led to a rapid recurrence of the patient's distress.

Venesection in Cerebral Hemorrhage.—There are three types of cerebral hemorrhage in which blood-letting might be advisable.

1. Ingravescent hemorrhage.
2. A sudden, serious hemorrhage.
3. Threatening recurrent hemorrhage.

I have no experience of venesection for ingravescent hemorrhage, but I should certainly be inclined to advise it should opportunity offer.

I have small doubt that venesection might, in otherwise suitable cases, be valuable at the onset of a sudden cerebral hemorrhage, but, unfortunately, the opportunity of performing it can hardly ever occur.

I have had the opportunity of using venesection in the third type of cerebral hemorrhage mentioned, that in which recurrent hemorrhage threatens. This patient, who was recovering from a primary hemorrhage three months' distant, I bled twice for the prevention of recurrence, on the appearance of such symptoms as vertigo, headache, paresthesia and high blood pressure. I believe that this treatment was of value in prolonging life, but it could not, in the face of highly-degenerated arteries, prevent an ultimate free hemorrhage, which caused sudden death.

Venesection in Nephritis.—The cases of venesection in nephritis, which have come under my notice, fall under the following heads:

1. Simple acute nephritis, with high blood pressure and signs of uremia, occurring in young people.
2. Uremic convulsions, due to chronic nephritis.
3. Chronic uremia, with high blood pressure, due to chronic nephritis.

In the first type quoted, the blood-letting was advised in order to relieve two conditions, the high blood pressure, and the toxemia induced by the disease (that is, assuming that the symptoms of so-called uremia are due to poisonous material circulating in the blood.) In this case the immediate result and the ultimate result were alike excellent, and I shall incline to a repetition of the treatment with the advent of a suitable case.

I have only seen the above case of this type, and I can not speak as to whether the bleeding gained its good result by relieving the blood pressure or the toxemia, or both. The mere relief of a fairly high blood pressure does not seem to account for the great relief of the other dangerous symptoms in such a case. Does venesection relieve an acute septicemia or sapremia, without a high blood pressure, for instance?

I have only one case of uremic convulsions to chronicle, and in this case venesection (twenty ounces) was of no avail. I note, with interest, that in this case the blood pressure was not high, for I am inclined to attribute the whole value of blood-letting to its influence on blood pressure rather than to any possible abstraction of *materies morbi.*

Of chronic uremia, with high blood pressure, I have three cases. In each of these venesection gave an immediately good result, followed by a rapid relapse in a few hours. As I stated above, venesection can not be expected to give any permanent results in cases where the heart and vessels are seriously degenerated. The circulatory system must retain the power of recovery if it would benefit by the short rest and the chance of regaining its equilibrium, conferred by venesection.

Venesection in Heart Stroke.—One case only, in which venesection was used, has come under my notice. The case was one of true insolation, occurring on a steamship in the Indian Ocean, not a case of mere heat exhaustion, such as we may see fairly often in the summer. The onset occurred while the man, a stoker, was asleep in his berth during a very hot night. When found he was comatose; temperature in the rectum, 107° F.; the skin pale and dry, the pupils widely dilated, and the pulse small and feeble. Cold water and ice were applied to the head and body. Brandy was given by the rectum, and liquid strychnine subcutaneously. By the use of ice water the temperature was reduced in half an hour to 104.5° F., but the patient still remained

comatose. His condition was one of extreme cardiac failure; the pulse being irregular, small and feeble; the superficial veins of the head and neck were full, and the face livid. It seemed probable that the heart was in a state of paralytic distention, and the venous system choked. He was then bled from the arm to about twenty ounces. Even while the blood was flowing, the good result was to be seen, the skin rapidly losing its lividity, and the pulse growing fuller and stronger. Evidently the relief afforded by the venesection had been sufficient to allow of the readjustment of the cardiac function. The temperature was now 105° F. The man eventually made a good recovery, with the aid of ice-water douches and full doses of quinine.

I do not mean to imply that blood-letting is a valuable treatment for insolation. The above case might apply to cardiac failure following hyperpyrexia from any cause. I have quoted this case as the most typical instance of a life saved by venesection that is within my knowledge, for this man was moribund prior to the venesection.

The late Professor Hughes-Bennett, of Edinburgh, one of the strongest opponents of the irrational use of venesection, advised the use of small blood-lettings to mitigate the pain and distress of the last stages of aneurism. The advice seems reasonable, and coming from such an authority may be worthy of trial.

Throughout this paper I have used the term blood pressure preferably to arterial or venous tension, for the reason that the former term conveys a more definite meaning than the latter. When we speak of arterial tension do we not really refer to the pressure under which the blood is contained in the artery? I do not speak of the actual tension of the blood, since I am not enough of a mathematician to follow so abstruse a question as that of fluid tension. If the term arterial tension refer to the strain upon the vessel wall, it may well involve us in contradiction. For if the arterial wall be muscular, elastic and healthy the blood pressure within the artery may be very high (as in acute nephritis), while the tension of the arterial coat remains low; and, conversely, if the arterial wall be diseased, a comparatively low pressure may well raise the tension of the vessel wall to breaking strain. For these reasons I prefer to avoid the term arterial tension, and to use the term blood pressure, as having a more definite meaning.

I have endeavored to show that clinical research affords many interesting lines of study to those of us who, being engaged in general practice, have neither laboratory nor hospital to interest them. There must be many more indications for venesection than those I have dealt with. I have merely taken for consideration certain cases which may be looked upon as types. In the case of any therapeutic agent it is necessary that we should formulate the typical occasions for its use; we need not, and should not, hold only to type cases, but should vary our formulæ to meet the needs of individual disease.

[Written for the MEDICAL BRIEF.]

Tuberculosis and Its Prevention.

BY FRANCIS EDMUND CLAY, M. R. C. S. (ENG.), L. R. C. P. (LOND.),
Fellow of the Guthrie Society.
Lewisham, London, England.

The question of the spread of tuberculous disease is of interest, not only to the bacteriologist and to the denizens of the pathological laboratories, but to the physician engaged in active practice, who is usually the intermediary between the pure scientist and the rest of the community. A layman has no time and no opportunity, even if he had the requisite knowledge, to study and digest technical reports, and, naturally, looks to his doctor for information concerning all that appertains to the maintenance of his health and that of his family. The physician, in this way, performs a most useful and important function, and it behooves him to keep well abreast with recent scientific knowledge, and to be true to the trust which is placed in him. This is especially the case with regard to tuberculosis, for there is no disease, acute or chronic, so productive of human suffering or so destructive of human life. Pulmonary phthisis, or consumption and tuberculosis, are so closely allied that the terms are not infrequently used as if they were

practically synonymous, but this is certainly a mistake. Some people, impressed by the confusion resulting from the employment of the word phthisis, have suggested dropping it entirely and substituting some such expression as tuberculous disease of the lungs. That, however, is not free from objection, for there are some cases of phthisis which are not tuberculous, at all events in an active sense. Take, for example, fibrous phthisis. This may have commenced with a tuberculous infection at the apex of one lung, but this is not invariably the case, and the inhalation of particles of irritating dust may have been the exciting cause. Again, at a later stage of the disease, especially if the fibrous tissue is undergoing calcification, the tubercle bacilli may have entirely disappeared from the expectoration, or they may have been replaced by various forms of streptococci.

In this paper I do not intend to confine myself to any particular disease of the lungs, whether tuberculous or not, but shall deal with the subject in its very broadest aspect. Tuberculosis is the same disease—modified, it is true, by structural conditions, and also by environment—whether it occurs in the meninges, in the peritoneum, in the lungs and pleura, in the joints, or in any other part of the body. The symptoms are different, and the mode of entrance of the bacilli into the system may be by different portals, but the disease is the same whatever organ be invaded, and whether the host of the parasite is man or monkey, beast or bird. Avian tuberculosis, in the mode of reaction of the bacilli to certain reagents, may differ slightly from human and bovine tuberculosis, but this is a difference of detail and not of principle.

The evidence of the transmission of tuberculosis from animals is somewhat conflicting, but no one will deny that it would be little short of madness to consume animal flesh impregnated with tubercle bacilli. In the same way, milk from a tuberculous cow should be rejected unless thoroughly boiled, and even then it would be better not to use it. It has been proved that the ingestion of any material which contains the tubercle of bacillus is a danger to the consumer, but the limitations of this risk have, as yet, not been completely defined. It is said that forty per cent of the children who die in hospitals die tuberculous, and although congenital causes may have some influence, they can not be regarded as the predominant factor. It is difficult to resist the conviction that the consumption of unboiled milk during the period which follows weaning, must exert a very powerful influence in bringing about the fatal prevalence of the disease at that period of life. The practical points which force themselves on our attention are that we should be extremely guarded in sanctioning the use of unboiled milk for children, and that we should be especially cautious in prescribing raw meat and meat juice in cases of infantile atrophy and dyspepsia. What we demand is unremitting sanitary precautions in the inspection, not only of dead meat, but also of living cattle. In the case of inspected stock, the injection of tuberculin may be employed as a diagnostic agent, and this mode of investigation in skilled hands gives reliable results. If an animal should prove to be infected it should be slaughtered and its carcass cremated by the plentiful use of petroleum, or some similar means. The question of compensation may present difficulties, but they can be overcome, and money spent in this direction is not waste, but true economy.

There is not a vestige of doubt that consumption is a communicable disease. The evidence in support of this view is partly clinical and partly experimental. The term "contagious" is vague and ill defined, and with regard to phthisis, must be held to be identical with the word "communicable." Scarlet fever, typhoid fever and syphilis are all communicable diseases, but they are contagious to a very different degree. Until the last thirty years phthisis was not regarded as a communicable disease, although little by little the view has gained ground that it is contagious to a very marked extent. In Germany phthisis is considered to be almost as infectious as the zymotic diseases, and in their hospitals cases of pulmonary tuberculosis are treated, not in the general wards, but in wards set apart for the purpose. In their prisons, a prisoner found to be consumptive, is at once isolated, and an elaborate process of disinfection is

resorted to in order to prevent the cell from becoming a center of infection. In Italy, consumption has long been regarded as a contagious disease, and when any one dies of this complaint, the bed and all the clothes of the deceased are destroyed, and the room, after being thoroughly cleaned and disinfected, is shut up, and is not again occupied for some time. The greatest terror exists amongst them as to the communicability of the disease. Phthisis is more likely to be communicated amongst the poor, with whom accommodation is more limited than amongst the well-to-do, who have the advantage of large and well-ventilated rooms.

In a large number of cases tuberculosis of the lungs is the direct outcome of inhaling dust containing dry bacilli, which, under favorable conditions with regard to warmth and moisture, are soon restored to activity, and lodging in the apex of the lung, where there is a limited range of movement, set up miliary tubercles, followed by caseation and the formation of vomicæ. The habit of spitting in the streets and in public conveyances is a source of such danger to the community that in almost every country legislative interference has been invoked to limit the practice. There has been a marked improvement in this respect of late years, and it is, perhaps, to be regretted that public prosecution is not more frequently the result of the infringement of so salutary a measure. It is comparatively easy to prevent the propagation of phthisis and other tuberculous diseases, but treatment is often unsatisfactory, and is, at best, a costly mode of procedure. In England, alone, the mortality from diseases classified under the head of tubercular amounts to from fifty to sixty thousand a year, whilst the cost to the community in poor rates may be set down as a million pounds, and the loss to the working classes in the shape of wages can not be less than ten millions per annum. Quite apart from the lamentable waste of life, the financial aspect is one of most serious importance, and any capital expended in attempting to wipe out this dire disease, the scourge of humanity, is properly expended, and will surely bring its reward, perhaps not at once, but in the near future.

Much might be done in the way of legislative enactments regulating the width of streets, the height of houses, and, above all, the preservation of open spaces. The establishment of public wash-houses has done much to minimize the frequency with which the washing and drying of clothes is carried on in small rooms. More might be done in this direction by the establishment of public workrooms, where on payment of a small fee, tailoring, bootmaking, and other similar employments might be followed. Overcrowding is not altogether confined to the poor. At many popular seaside resorts the cheaper lodging-houses are, during the season, disgracefully overcrowded, and the same assertion may be made with respect to some of the large hotels. Consumption and other tuberculous diseases are more common in large towns than in sparsely populated localities, and in towns it is the densely inhabited, poorer districts which suffer most. Sufficient air space for the inhabitants is more likely to be found in the houses of the well-to-do than in the dwellings of those to whom the question of the ability to find the rent is of more pressing importance than the sanitary state of the rooms, but it must be admitted that this is not always the case. It may, reasonably, be urged that legislation and legislative enactments do not fall within the province of the practising physician. This is undoubtedly, to a certain extent, true, but matters appertaining to the health of the community fall within the scope of his professional duties, and he would be wanting in public spirit were he to neglect his obligations in this respect. Although the average layman naturally resents medical interference in the range of pure politics, he is ready enough to listen to an expression of opinion on a purely technical point when backed by an intimate acquaintance with the subject, and a desire to be of some service. For the physician to carry weight and to make his influence felt, he must be perfectly clear in his own mind as to what it is that is wanted, and to be able to explain, logically and concisely, the reasons for the faith that is in him. The points to be aimed at, and the arguments to be employed, will probably vary somewhat with the locality and the opposition

to be encountered, and it is as well to remember that progress is often slow, and that success can be insured only by much diplomacy, and the exercise of considerable tact. People who will not vote the whole ticket may often be found amenable to reason on one or more points which appeal to them personally. By letting them go slowly at first, a whole-hearted support will, ultimately, be secured.

These are some of the practical points to which I attach most importance:

The inclusion of consumption in the list of notifiable diseases. In my own borough of Lewisham voluntary notification of phthisis is the custom; that is, we report to the Medical Officer of Health, with the consent of the patient.

The official announcement of the fact that, in the event of a person having died of consumption, the rooms occupied by him will be disinfected by the sanitary authorities free of charge. The facilities for disinfection should extend to any dwelling which has been vacated by a consumptive person, and should be enforced in the case of hotels and lodgings at health resorts frequented by sufferers from chest diseases. In my district disinfection is performed by the sanitary authorities free of charge on the recommendation of the physician.

To make it illegal to let any house or room in which any person within two months has suffered from consumption, without having had it properly disinfected.

To make it an offense, punishable by fine or imprisonment, for any person letting a house or room to willfully conceal or deny that there has been consumption in the house.

To call the attention of shipping agents to the fact that there is danger to a healthy person occupying the same cabin with a consumptive, especially on long voyages, and when, from the inclemency of the weather, the passengers are not much on deck.

To make it compulsory for a consumptive person, taking a long voyage by sea, to notify the nature of his complaint before starting.

To call the attention of railway companies, on lines connected with health resorts for consumptives, to the necessity for having the sleeping carriages carefully cleaned with disinfectants, and, above all, thoroughly aired.

To insure the removal of hospitals for consumption from cities to convenient and open suburbs. The out-patient department might, for convenience, be retained in town, but there should be no in-patients. Hospital cars to ply from certain fixed points to the hospital and back, and not be available for the general public.

To insure the exercise of greater care in the inspection of carcasses intended for food, and the compulsory rejection of those exhibiting indications of the tuberculous disease.

To insure the rejection, as an article of food, of the milk of tuberculous cows.

To insure the inspection of herds by paid officials, with the view of detecting tuberculous disease, and isolating or destroying infected animals.

To insure the prevention of overcrowding amongst animals intended for consumption as food.

To prevent overcrowding by regulating the amount of cubic space allotted to each person in common lodging-houses, workshops, etc.

The extension of wash-houses, and the establishment of places where certain trades, such as tailoring and bootmaking, could be carried on by the payment of a small fee.

Back-to-back houses to be condemned, and the height of houses in cities restricted in proportion to the width of the streets.

Blind alleys to be opened out, and the custom of building houses at right angles to the length of the streets, forbidden.

Dusty occupations to be strictly regulated, so as to minimize the danger to those who are compelled to follow them.

Convents, and other religious communities, to be periodically inspected by some independent authority, with the view of ascertaining the general condition of the health of the inmates, and suggesting such sanitary and other measures as may seem necessary.

With regard to matters of hygiene affecting the tuberculous, I think that the medical man practising in a community might make it his personal care to dissem-

minate, by papers in the medical press or by lectures or pamphlets, or even leaflets, such information as, in his opinion, may prove instructive and beneficial in preventing the spread of disease. To this no ethical objection can reasonably be taken, if the object aimed at is not personal advancement, but the maintenance of the health of the population. In London and many parts of England, most of the leading hospitals distribute freely leaflets, giving advice on the feeding and management of young children, and this may be regarded as a precedent.

The examination of the sputum for tubercle bacilli by sanitary authorities gratis, on the recommendation of the physician.

The following are the points on which I lay most stress. I may say, at once, that I do not claim them as original, and that they are adapted from similar rules and aphorisms contained in a work on the "Prevention of Consumption," by Dr. Murrell, of the Westminster Hospital, London.

1. No one should sleep in the same room with a person suffering from phthisis, especially when the expectoration is abundant.

2. The temperature of the room occupied by a consumptive person, should not be high, especially when he is confined to bed, and efficient ventilation should be secured, preferably by means of open windows.

3. The patient should expectorate into a spittoon containing an efficient disinfectant. The expectorated matter should be destroyed by mixing it with fine coal and burning it in the fire.

4. The pocket-handkerchiefs used by the patient should be thrown into a bucket containing a disinfectant solution, and should be scalded before being sent to the wash. Instead of the ordinary handkerchief, a paper substitute, or pieces of rag, may be used, and these should be burnt.

5. It should be remembered that the risk of conveying the disease from the sick husband to the healthy wife who nurses him is great, and *vice versa*.

6. The wife who nurses a husband suffering from consumption should get fresh air as much as possible, and should do all in her power to maintain the condition of her own health.

7. Wind instruments and other articles which have been used by a consumptive person, to be destroyed when no longer required, or not to be used by healthy people without previous disinfection.

8. Not to travel on board ship in the same cabin with a consumptive person. Apply to the surgeon for another berth, or for an order to have the sick person removed to the ship's hospital.

9. Food should be well cooked, not only superficially, but throughout.

10. In the case of tuberculous children, or of people predisposed to phthisis, boil all milk previous to use.

11. People predisposed to phthisis should select as a place of residence a house on a gravel soil, preferably on a slope and facing south.

12. Those predisposed to phthisis should select non-sedentary occupations, and should be encouraged to spend as much time as possible in the open air, and, above all, in sunlight.

13. People should be taught to value the importance of amusements of all kinds, and to recognize the danger of leading monotonous and depressing lives.

14. The children of phthisical parents should devote reasonable time to athletic exercises, and should not be allowed to follow sedentary occupations.

15. These children should be encouraged to migrate, and not to live in the house which their parents occupied.

[Written for the MEDICAL BRIEF.]

Ringworm and Its Treatment.

BY A. WINKELREID WILLIAMS, M. B., C. M. (EDIN.), D. P. H. (LOND.),

Physician to the Skin Department, Royal Alexandra Hospital for Sick Children.
Brighton, England.

No. II.

During the past ten years many workers have endeavored to perfect X-ray treatment as an ideal mode of epilation. The difficulty of estimating the quantity, and, above all, the quality of the rays, has been a stumbling block. Exposures short of producing complete temporary baldness are absolutely useless, and it is an easy

thing to overstep this point and produce an X-ray burn, followed by permanent baldness. Sabourand and Noiré have, in a great measure, overcome this difficulty by the introduction of their platino-cyanide radiometer. This gives a great margin of safety, but it is not absolute, and occasionally cases have gone wrong, even when the radiometer is properly used. This necessitates warning the parents of this possible accident, or running a risk of an action for damages. Dr. J. M. H. MacLeod has devised an apparatus which further checks the Sabourand-Noiré radiometer; it is described in the *British Medical Journal*, September 16, 1905. The author, after seeing this at work, has erected a similar installation, and finds it most valuable. Undoubtedly, X-ray treatment is the most certain and rapid of all ringworm treatments, but, despite the most elaborate and expensive apparatus, it is not devoid of risk, and until greater perfection in measuring the dose is obtainable it will be found that many parents will not consent to its use. Moreover, in children under five years, and in cases where active inflammatory impetiginous conditions exist, X-rays certainly should not be used. It is evident that the older therapeutic measures have still the greater place in ringworm treatment.

It is of value and interest to note various methods that have been recommended, from time to time, by different authorities, some of which are here given:

DR. ALDERSMITH.

Croton Oil Treatment.—I. When applicable:

1. Chronic patches that have resisted treatment for a long time.

2. Moderate-sized recent patches, when rapid cure is imperative.

3. Old, desseminated ringworm, with isolated hairs and black dots.

II. *Modus operandi:*

1. Patches.—Clip hair short all around patch and mark it out with skin pencil. Surround patch with layer of fat. Paint patch with croton oil and allow to dry, and then poultice freely with hot linseed meal poultices. Next day empty any vesicles or bullæ. Examine and see if sloughing; if no sloughing reapply, and continue until a kerion-like condition is set up, then epilate and apply some mild antiseptic, *e. g.*, glycerine and carbolic acid.

2. Disseminated Hairs.—Aldersmith's needle used. Drop in croton oil, seven drachms, and carbolic acid, one drachm; colored red with alkanet, and carefully insert needle down to bottom of follicle. Next day remove stump with forceps.

N. B.—It is not safe to needle hairs close together.

Another Treatment.—Very valuable in diffuse ringworm of scalp:

1. Shave head.

2. Apply three, four or five times a day the following *inflammable* lotion:

℞ Salol.....60 grains.
Acid Boric ..... 6 drachms.
Ether Meth..... 5 ounces.
Ol. Rosmar..... 1 drachm.
Spt. Vini Meth .....ad.....20 ounces.

PROFESSOR MCCALL ANDERSON.

1. Cut hair short.

2. Epilate. (*a*) From edge of patch. (*b*) Extend to center.

3. After epilating one square inch, rub in *at once* some paraciticide ointment.

PROFESSOR BESNIER.

1. Keep hair very short.

2. Epilate and keep epilated a zone around patches.

3. Anoint with vaseline and curette away all epithelial debris.

4. Wash and soak patches well with alcohol, 100.0; boric acid, 1.0; chloroform, 5.0.

5. Thoroughly curette patch through epithelium to papillæ, *i. e.*, until it bleeds well.

6. Stop bleeding by pressure with sterilized cotton wool sponge.

7. Again wash with lotion (4).

8. Apply on cotton pledget Van Swieten's solution, 100.0; glaceal acetic acid, 1.0 (V. S.'s solution: Hydrarg. perchlor, 2 grains; alcohol, 3 drachms; water 4 ounces).

9. Cover patches with acetic acid, 1 in 100, vigos plaster.

10. On reappearance of diseased hairs repeat epilation and scraping.

DR. W. S. CORLETT.

1. Cut hair short.
2. Shave patches.
3. Wash regularly.
4. Epilate when possible.
5. Use various antiseptic ointments.

DR. RATCLIFFE CROCKER.

1. Cut hair short.
2. Wash head three times weekly with soft soap and weak carbolic lotion.
3. Epilate, in older children, as much as can be tolerated.
4. Rub in antiseptic ointment, *e. g.:*

℞ Cupr. Oleat .....1 drachm.
Lanolin.....5 drachms.
Parolein.....3 drachms.
Or else a 5 to 20 per cent Oleate of Mercury.

Another Method—Apply to patch Coster's paste with a hard brush, and in three days' time tear off scab.

Another Method.—After cutting hair, shave patches and area three-quarters of an inch around them, and then paint daily for a week with ten grains salicylic acid in one ounce of collodion. Remove thick collodion skin and attached hairs with forceps. Shave again and reapply.

DR. FOULIS.

1. Cut hair short.
2. Wash with ten per cent carbolic soap.
3. Rub areas with turps. by finger for three or four minutes, until part stings, then paint with two or three layers of tincture of iodine. Repeat night and morning in severe cases, or every night in less severe.

DR. G. HENRY FOX.

1. Cut hair short.
2. Shampoo head thoroughly each day.
3. Epilation most important. (*a*) Long hairs for a zone around patch; (*b*) at leisure, hairs of patch.
4. Rub in twice daily sulphur ointment, or oleate of mercury ointment, or ten per cent chrysarobin ointment.
5. After patches look healthy allow hairs to grow, and apply daily five per cent salicylic acid in oil.

PROFESSOR HALLOPEAU.

1. Cut hair short.
2. Wash every morning with soft soap.
3. Friction with

℞ Spt. Camphor. .....125.0.
Ol. Terebinth ..... 25.0.
Liq. Ammon.... ..... 5.0.

4. Apply one per cent iodine in vaseline.
5. Wear gutta percha cap during day.
6. At night reapply iodine ointment.

DR. HARRISON.

1. Cut hair to one-quarter of an inch.
2. Rub affected parts night and morning with small quantity of

℞ Pot. Caustic..... 9 grains.
Acid Carbol. .....24 grains.
Lanolin..... ½ ounce.
Ol. Coca Nuc..... ½ ounce.
Ol. Caryoph..... ..... q. s.

3. Anoint rest of scalp with

℞ Ung. Borac.....2 ounces.
Ung. Eucalypt .....2 ounces.
Ol. Caryoph ...:..... ½ drachm.
Ol. Coca Nuc .....ad .....6 ounces.

DR. ALLEN JAMIESON.

1. Keep hair short.
2. Wash daily, using fluid superfatted soap with hot water and flannel.
3. Starve fungus by free application of antiseptic ointment, *e. g.:*

℞ Sulph. Precip..... 1 drachm.
Hydr. Am. Chl. .....80 grains.
Lanolin ..... 1 ounce.

or else

℞ Oleat. Cupr.....50 grains.
Lanolin ..... 1 ounce.

4. Every other day clean up seborrhea, etc., of scalp, and prevent infection by using all over scalp:

℞ Acid Tannic..... 1 drachm.
Acid Carbol .....5 grains.
Cold Cream.....ad.....1 ounce.

PROFESSOR KAPOSI.

1. Rembve scabs, scales, etc., by oil poultices, with or without balsam Peru, carbolic acid, or naphthol.
2. Wash thoroughly with soft soap.
3. Daily epilation.
4. Apply paraciticide, *e. g.:*

℞ Ol. Rusci .....15.00 parts.
Spt. Sapon Kalen .....25.00 parts.
Sulph. Precip .....10.00 parts.
Spt. Lavand..... 0.50 parts.
Bals. Peru..... 1.50 parts.
Naphthol ..... 0.50 parts.

DR. LIVERING.

1. Cut hair short.
2. Wash head twice weekly.
3. Rub on, night and morning, antiseptic ointment, *e. g.*, hydrarg. oleat, ten to fifteen per cent.

DR. LYLE.

For chronic cases:

1. Keep head shaved.
2. Scrape patches with sharp spoon.
3. Rub well in with cotton swab, argent. nit. one drachm; spirit (proof), one ounce.

4. Twice weekly scrape away black layers and reapply argent. nit.

5. Treat rest of scalp with five per cent hydrarg. oleat. in oil.

MR. MALCOLM MORRIS.

1. Cut hair short for one inch around patches.

2. Epilate.

3. Avoid all soap and water washing, but start treatment by cleaning all scales, etc., off with soft soap and spirits.

4. Rub in ointment—ten grains chrysarobin, one ounce—but leave no excess upon the skin. Continue use of ointment until tenderness and red halo develop.

5. Then apply ungt. acid boric.

6. When inflammation reaction subsides, reapply chrysarobin.

7. After three attacks chrysarobin inflammation, try various ointments in succession, e. g., (*a*) sulphur, (*b*) mercury, (*c*) iodine.

DR. STEELE PERKINS.

1. Shave affected area.

2. Rub in common salt and vaseline, night and morning, until part becomes very sore.

3. Apply soothing remedy.

SIR WM. JENNER.

℞ Sodii Hyposulphat.....120 grains.
Aquæ..... 1 ounce.
Cover with oil silk.

DR. QUINQUAUD.

1. Spray patches with methyl chloride and curette, to remove all scales, scabs and such debris.

2. Apply to whole head, more freely to patches:

℞ Hydrarg. Biniodid..... 3 grains.
Hydrarg. Bichlor.....15 grains.
Alcohol. 90%..... 1 ounce.
Aq. Destil .....ad..... 8 ounces.

3. Cover patches with round piece of plaster:

℞ Hydrarg. Biniodid..... 3 grains.
Hydrarg. Bichlor.....15 grains.
Emplast. Saponis ..... 8 ounces.

4. Cover with a linen cap.

5. In forty-eight hours remove plaster, cleanse scalp, reapply lotion and plaster. Repeat until cured.

DR. SABOURAUD.

1. At night keep patches covered with tampon soaked in solution of $CaCl_2$ in water (three drachms in ten ounces), covered with gutta percha tissue.

2. Wash in morning with soap and water and cover with empl. plumbi for day.

3. Twice a week paint with tincture of iodi.

DR. JOHN V. SHOEMAKER.

1. Cutting hair very little good. Epilation absolutely useless.

2. Avoid water on scalp, but wash area and skin around with alcoholic solution of borax.

3. Sponge areas daily with a weak alcoholic solution of thymol, naphthol or mercuric chloride.

4. Apply fifty per cent boroglyceride. If marked improvement does not follow in a short time, rub well in oleat of copper, one in five or ten, and occasionally alternate with oleat of mercury.

DR. PYE-SMITH.

1. Cut hair short, clean up crusts, scales, etc., with poultices.

2. Cleanse patches with soap, water and flannel, and then rub in ungt. hydrarg. am. chlor.

3. Anoint rest of scalp with carbolic oil (one in fifteen or one in twenty).

DR. LOUIS STARR.

1. Cut hair short.

2. Wash daily with soap and water, followed by saturated and boric solution.

3. Apply antiseptic ointment twice daily, *e. g.:*

℞ Sulph. Precip.....1 drachm.
Cold Cream .....2 drachms.
Lanolin.....6 drachms.

4. Every four or five days apply, with stiff brush, Coster's paste (iodine, two drachms; light oil of wood tar, six drachms).

DR. P. G. UNNA.

1. Cut hair short.

2. Paint round head a band of zinc jelly.

3. Rub well all over scalp:

℞ Chrysarobin..... 5.0 parts.
Acid Salicylic..... 2.0 parts.
Amm. Sulpho-Ichthyolate..... 5.0 parts.
Ung. Simple.....88.0 parts.

4. Cover head with gutta percha tissue and fix with zinc jelly and bandage.

5. Tie flannel cap over all.

6. Every twenty-four hours for next four days open gutta percha tissue by side slit, clean scalp and reapply the ointment. Cover slit with zinc jelly.

7. After four days remove cap, but keep jelly bands, wash off chrysarobin and for three days treat with five per cent amm. sulpho-ichthyolate ointment.

8. At end of seven days wash off jelly and thoroughly cleanse scalp with oil and soap.

9. Repeat above treatment four times and expect a cure.

DR. NORMAN WALKER.

1. Cut hair short (epilation—theory correct, practice useless).

2. Wash frequently with antiseptic soap.

3. Thorough massage of ointment into scalp with thumb, *e. g.:*

℞ Sulph. Precip..... ½ drachm.
Hydr. Am. Chlor..... ½ drachm.
Acid Salicylic.....20 grains.
Lanolin..... 1 ounce.
Vaselin..... 1 ounce.

Or,

℞ Chrysarobin..... 3 drachms.
Cera Flav..... 2 drachms.
Lanolin..... 5 drachms.
M.: Melt, mix, and shape into a cosmetic rod.

RINGWORM OF NAILS.

1. Scrape nail down as thin as possible. Cautious use of liquor potassæ helps.

2. Clean and scrub nail surface, round and under nail with liquor potassæ. (Painful, but necessary.)

3. When patient can not bear potash cleansing any longer, wrap nail and finger tip in lint, thickly spread with

℞ Acid Salicylic.....40 to 120 grains.
Emplast. Plumbi..... ½ ounce.
Vaselin..... ½ ounce.

and keep this constantly applied.

Another Treatment.—1. Soak nail under oiled silk for fifteen minutes, with

℞ Liq. Potass.....½ ounce.
Aq. Destil.....½ ounce.
Pot. Iodid.....½ drachm.

2. Apply on lint, under oiled silk, for twenty-four hours:

℞ Hydrarg. Perchlor.....4 grains.
Spt. Vini Rect..... ½ ounce.
Aqua..... ½ ounce.

3. Reapply until cured.

Another Treatment.—Remove entire nail and dress with some antiseptic ointment.

RINGWORM OF BEARD.

There is no doubt about the extreme value, in fact, necessity, of careful and painstaking epilation in this region. I have invariably found the following treatment rapidly successful.

1. If much scabbing, remove by soaking chin in kerosene, or if patient objects to this, with boric starch poultices.

2. Smear chin with salicylic oil (five per cent), and then carefully epilate infected regions, picking out all hairs loosened by suppuration, and immediately after epilating one square inch rub on

℞ Hydrarg. Perchlor.....3 to 5 grains.
Lanolin.....4 drachms.
Aq. Rosæ.....2 drachms.
Ol. Amygdol.....2 drachms.

3. Spray rest of chin with

℞ Sanitas Oil..... ½ ounce.
Spirit. Vini (Proof).....10 ounces.

Patient to wash chin, keep hair clipped short or shaved; then apply ointment to infected areas, and use spray to rest of chin, and same to be epilated three times a week.

INGUINAL AND CRURAL REGIONS.

1. Wash with soft soap twice daily.

2. Sponge with ether.

3. Freely sponge with freshly-prepared solution of sulphurous acid.

4. Dust with boric acid, one drachm in one ounce of Fuller's earth, or else use some antiseptic ointment.

RINGWORM OF BODY GENERAL.

Wash areas with soft soap twice daily, and paint with tincture of iodi three times a week, and apply twice daily, after washing, some antiseptic ointment.

GENERAL HYGIENE.

Isolation of infected cases is, theoretically, the correct procedure, but the long duration of the disease makes it almost impossible, in many cases.

In large towns ringworm schools or school rooms are practically necessary or the stamping out of the disease is impossible. If cases attend ordinary school they must have entire scalp closely clipped and completely smeared with antiseptic ointment, and be covered with cotton skull cap. They must go to school one-half hour before the other children; a teacher should receive their hats and put them in a special place. The infected children must be dismissed before the others, and it should be seen that they return home and not linger about the school or playground. A trained teacher or nurse should examine weekly the heads of all pupils, and any showing scurfiness,

etc., to be at once referred to a medical man.

Infection is favored by damp and ill-lighted rooms, and by not exposing the scalp to light. Seborrheic conditions of scalp especially conduce to ringworm infection.

Children exposed to infection should have scalp frequently washed, well dried, and, after washing, a little pomade applied to scalp (not hair shafts) by partings of the hair in several directions. One of the best pomades is Unna's Ungt. Pomadini, *i. e.:* Ol. sherbrom, 2.0; ol. amydol, 4.0 (or in winter, 6.0); ol. rosæ, q. s.

To this may be added, if opportunities for infection are very great, three per cent of sulph. precip. and one or two per cent of resorcin.

Violent hair brushing to be avoided and combs should have rounded teeth, wide apart.

The children exposed to infection should be kept in the open air as much as possible, and, excepting during very hot sunlight, should wear no hats.

[Written for the MEDICAL BRIEF.]

Diagnosis and Therapeutics of Pneumonia.

BY L. A. NIPPERT, M. D.,

Clinical Professor of Medicine in the Medical Department of the University of Minnesota. Minneapolis, Minn.

Symptoms of pneumonia are so variable, depending on the severity of the infection, on the age and temperament, that the disease may be diagnosed on sight, and again may remain unsuspected for days.

The facial expression indicates a severe disease, the moving of the wings of the nose, the expiratory moan, the cutting pain in the side, compelling the patient to avoid the slightest motion; the rusty sputum and high temperature present a different picture from that of the old man who consults you at your office, feeling the need of a tonic. No pain, no cough, not aware of any shortness of breath, no fever, but a slightly accelerated pulse, and a consolidated lobe of the lung. The latter patient, however, is in a much more dangerous state than the former.

This is illustrated in the following case: An old lady, with the typical symptoms of pneumonia, lay for three weeks at the point of death. She finally recovered. Two years later, after a slight feeling of illness for several days, she attempted to go downtown. She returned feeling weak. I saw her a few hours later. She made no complaint whatever except that of exhaustion. On examination, the lower lobe of the right lung was found to be solid. She again had pneumonia, from which she recovered in two weeks.

The diseases which we have to consider in the differential diagnosis of pneumonia are pleurisy, empyema, tubercular consolidations, meningitis, and we should not lose sight of the fact that cholecystitis and even appendicitis, have been diagnosed when pneumonia was the ailment. The mode of onset, physical signs, and if in doubt, the use of the exploratory needle —which latter will also determine the character of the effusion—will distinguish pleurisy and empyema from pneumonia. Tubercular consolidations are not as extensive, the daily temperature curve more variable, and if located in the apices bacilli are usually found in the sputum. If affecting one of the lower lobes, there may be an extensive tubercular infiltration and no bacilli. Acute cholecystitis may, at the beginning, give rise to the same symptoms as pneumonia, except the marked acceleration of respiration and absence of the expiratory grunt. The same may be said of appendicitis, especially in children, in which the pain of pneumonia, even in apex pneumonia, is frequently referred to the abdomen.

That the meningeal symptoms of pneumonia overshadow all others in some patients, is shown best by quoting the following case:

B. S., a delicate girl of nervous temperament, was taken suddenly with a severe headache, vomiting, and partial loss of consciousness, not answering any questions for three days, not asking for anything to eat or drink, with headache, irregular pupils, bowels constipated; she presented all the symptoms of meningitis until about the fourth day, when acceleration of the respirations was noticed. On examination the upper lobe of one of the lungs was found to be consolidated. The

disease ceased by crisis and she made a perfect recovery. Some years later the same patient had another attack, in which the symptoms were again so markedly the symptoms of meningitis that a diagnosis of meningitis was made for the second time, and yet the course of the disease showed it to be pneumonia, from which she recovered.

In considering the therapeutics of pneumonia, prophylaxis is the first step. Careful protection from the inclemency of the weather, especially during the east winds of spring, and cleansing of the mouth and nose by antiseptic solutions, preventing the introduction of pneumococci into the air passages. The sputum of the patient should be destroyed, as in tuberculosis. As in most self-limited diseases the tendency is toward recovery, and the majority will get well without treatment, while some will succumb in spite of all our efforts. A number will recover under judicious care who would not survive if left alone.

I know of no remedy which will abort the disease, neither quinine nor ergot, nor guaiacol, and the salicylates have proven reliable in my hands. Specific treatment by sera is yet in the experimental stage. And even "One Hundred Cases Without a Death" is no criterion of the efficacy of any abortive treatment, unless similar results can be obtained by other observers.

A bright room, pure warm, moist air, a comfortable bed, light nourishing diet, tepid sponge baths, a thin cotton vest, without impermeable cover, abundant water, with fruit juices or claret, freedom from disturbance and watchful supervision under an experienced nurse, are of prime importance. To stimulate secretion and excretion, calomel, followed by a saline, has held its place for half a century. After free catharsis has been produced, liquor ammonia acetatis and spirits of niter are the only drugs which the writer uses as a routine. The physician who, in his own case, has obtained marked relief of pain from the use of the mustard plaster, will not despise it as an old woman's remedy.

In asthenic cases an ice pack to the affected side is a friend indeed, while ice to the head relieves headache. Sponge baths are efficient in relieving the ill-effects of high temperature. Small doses of caffeine give much comfort, if employed in the first two days, but should not be used after consolidation has been completed. In the first stage, Dover's powder, or if the pain be severe a hypodermic of morphine, will bring relief from pain and induce rest. Later on, any form of opiate should be considered dangerous and used with the greatest care, if at all.

The majority of patients do not need alcoholics. Alcohol, as well as strychnine, should be administered judiciously, excessive doses should be avoided. A bitter tonic, like gentian, combined with essence of pepsin, stimulates and promotes digestion, and prevents the accumulation of distressing gases in the stomach and bowels.

Indication of heart failure during the crisis should be dealt with vigorously. A solution of camphor in oil, given hypodermically, and combined with hot salt solution by rectum or by hypodermoclysis, is a powerful and often lasting stimulant. Except in cases of edema of the lungs, in which it has proved a life saver, oxygen has not fulfilled the writer's expectations.

To recapitulate: Minute attention to the details of nursing, watchful care of your patient, combating conditions as they arise, with avoidance of interference with nature's effort, and of overstimulation, has, I think, given me as low mortality from pneumonia as I have seen quoted from other and more aggressive forms of treatment.

The Senile Prostate.

BY LEWIS SCHOOLER, M. D., LL. D.,

Professor of Surgery in the College of Medicine of Drake University.
Des Moines, Iowa.

Among the majority of practitioners there seem to be two ideas most prevalent regarding the above subject. One, that nothing can be done for the patient with an enlarged prostate, and the other, that every enlarged prostate should be immediately removed.

As in many other subjects, perhaps the middle ground is the safest. Many pa-

tients have suffered from an enlarged prostate so long that it is impracticable to resort to an operation looking to the complete removal of the gland. Those persons who have had the bladder distended for a great length of time, with, perhaps, more or less infection, have suffered almost irreparable injury to that organ; therefore they are feeble, broken down, and suffering from infection and illy-prepared to undergo an operation of this character.

Under these circumstances, it is much better to try the plan followed by Eastman, of Indianapolis, viz., inserting and retaining a large catheter, thus procuring drainage and enabling the surgeon to apply local treatment to a bladder that has largely lost its tonicity. This, of course, should be done at the hands of one who is competent, and under the most rigid asepsis, and, if possible, give the bladder an opportunity to regain its tone and remove the source of infection.

Another method that may be pursued in cases of this kind, is by performing the operation at two sittings. The first contemplates an opening through the perineum, and inserting a tube through the neck of the bladder, after the manner of the median lithotomy operation. This gives good drainage, an ample opportunity for inserting a large drainage tube, and if there is hemorrhage from the bladder after evacuating so large an amount of its contents, it affords sufficient opportunity for draining away the blood as it is poured out, and prevents the accumulation of clots. A little later, if the patient recovers sufficiently, and the bladder is likely to be of service, the gland may be removed, either in its entirety or one side may be selected and the other be allowed to remain.

An enlargement of the gland is not always a criterion of the amount of difficulty it produces. There are many very large prostatic glands that do not occasion any trouble, but the inexperienced surgeon, finding a gland of this kind, is very likely to recommend immediate operation, regardless of the condition of the patient.

The operation, when done at two sittings, is sometimes referred to sneeringly as the "picket fence" operation, as though the patient had fallen astride of the fence and punctured the bladder. The resemblance is not very striking. One is an unfortunate accident, the other is a rational procedure, calculated to give great benefit to the sufferers of this class.

If the bladder does not regain its tone, and the patient does not rally sufficiently to warrant the second operation, he is at least relieved while he lives from the terrors of an over-distended bladder.

In younger men, say between the ages of fifty and seventy, where retention is only occasional and sometimes due to errors in diet, exposure, cold, or habits of the individual, catheterization at frequent intervals, sometimes affords great relief. But if the patient is in good condition ,and the catheter is needed oftener than once in three or four months the glands should be removed, and in this class of cases the operation may be completed at a single sitting.

Incidentally, there is no simple procedure so bunglingly managed in the hands of the majority of practitioners as the introduction of a catheter. The surgeon of large experience is frequently surprised at the meager equipment of the general practitioner for dealing with cases of this character. He usually finds only an ordinary catheter, which is devised for the purpose of emptying the bladder.

I believe that it is better practice to use the soft catheter to evacuate the bladder. If they have a prostatic catheter or a Lohenstein catheter, or filiform bougies with a conductor, they fare better, and time can then be taken to ascertain whether a prostatectomy is immediately demanded. Every surgeon of large experience has had brought to his attention patients who have had retention for the first time, in which ineffectual but forcible measures had been resorted to for their relief, with the result that numerous false passages existed. These are frequently more dangerous than the difficulty from which the patient suffers, and are in bad condition, sometimes, to undergo a complete prostatectomy.

An improvement along these lines is demanded in the teaching of all the schools, and the student should have actual practice in the use of the catheter.

Two Interesting Cases of Fracture of Lower Leg.

BY E. F. DEAN, M. D.,

Professor of Anatomy in the Dental Department of the University of Denver; Demonstrator of Anatomy in the Denver Gross Medical College; Surgeon to the City and County Hospitals. Denver, Colo.

The two following cases present several interesting features, from the standpoint of age and habits of the patients. In the first, dissipation, alcoholism and irregular hours; in the second, steady habits and good health prevailed throughout life, the first recovering under great disadvantages, and the second dying very suddenly.

J. R., aged sixty-three, a man of dissipated habits, and who indulged in not only alcoholic liquors, but crude alcohol, and who had been a life-long sufferer from hip disease, fell on the street while in an intoxicated condition and fractured his right leg half way between the knee and ankle. He walked on this leg for several hours and, finally, dragged himself home and went to bed, refusing the services of a physician. The following morning a physician was called, with his consent. I found every evidence of thrombosis present on my first examination of the leg; this was followed by gangrene.

The limb was placed in a fracture box and watched for twenty-four hours, at the end of which time amputation was necessary. The leg was amputated half way between the hip and knee, finding it imperative to keep away from the hip on account of the existing hip disease. It was also essential to keep above the affected area.

Recovery was rapid and uneventful, after having an attack of delirium tremens. The remarkable feature of this recovery is that the patient had fairly lived on alcohol and whisky, had had for many years a disease of the right hip, and that he dragged the fractured leg around for hours, and remained without any treatment whatever for one night. No difficulty was experienced in treatment on account of the hip-joint trouble.

Case 2.—C. C., aged sixty-five, received a fracture of the lower leg, about three inches above the ankle; injury followed a street car accident. A simple fracture of both bones was found. The usual treatment was carried out and the patient appeared to start well on the way to recovery, when he developed a pulmonary thrombosis and died suddenly at the end of the first week.

Diagnosis and Treatment of One Form of Chronic Constipation.

BY BERNARD ASMAN, M. D.,

Professor Diseases of the Rectum, Kentucky University Medical Department. Louisville, Ky.

A positive diagnosis is easily made by means of the Laws pneumatic sigmoidoscope in those cases of chronic constipation caused by acute flexure at some point in the large bowel. But before beginning the treatment a careful and thorough examination of the patient must be made, even though the primary cause is found to be an acute flexure in or about the sigmoid, as is the case in the majority of instances of severe chronic constipation. The stomachic or intestinal indigestion, as well as deficient intestinal, pancreatic, or hepatic secretions, must be investigated and treated. Should there be chemical changes producing fermentation and excessive flatulence, some antiferment, such as carbolic acid and glycerine, can be advantageously used. If the fecal matter, when discharged, is very dry and solid, some benefit may be derived from taking large quantities of water between meals, or just before meals if there is a great deal of mucous secretion in the stomach. Peristalsis, if deficient, will require stimulation. Directions regarding diet, exercise, etc., must be explicit. The patient must be regular in his daily habits, methodical in regard to meals, work, recreation, especially punctual in regard to time of defecation. Habit in this respect counts for much, and if neglected will defeat almost any plan of treatment.

The acute flexure can be relieved by repeatedly distending the bowel with either water or air, preferably the latter.

This can be done after placing the patient in the knee-chest position and inserting the sigmoidoscope by slowly and carefully pumping the air into the bowel by means of the pneumatic attachment to the sigmoidoscope; or, better, by means of a hard rubber rectal tube about four inches long attached to the tube of a multinebulizer. In this way the flow of air can be carefully regulated, being allowed to pass into the bowel very slowly, thus separating the folds and finally lifting up the descended loop of bowel out of the pelvic cavity. Loops of small intestine take its place, the sigmoid being held up in its normal position and the acute flexure being obliterated for a considerable time. That this takes place is proven by the fact that after a treatment of this kind the following evacuation will be free and easy, no matter how much difficulty or straining the patient has been accustomed to during defecation. Great care must be taken in the first few treatments to avoid too forcible dilatation. It must also be remembered that if much air is left in the bowel the patient will suffer considerable discomfort following the treatment. Soon, however, the patient becomes accustomed to treatment and the distention can be made more and more complete.

An advantage of the multinebulizer lies in the fact that the air can be impregnated with a solution which will act as an intra-intestinal stimulant to peristalsis. These treatments in the average case should be given every second day for the first week or ten days, after which twice a week is sufficient, and should be kept up, according to the severity of the case, from six to twelve weeks.

Massage, especially mechanical vibratory massage, furnishes a most excellent adjuvant in the treatment of these cases. It can be applied over the abdomen, following the course of the colon, up and down the spinal column as a general stimulant, and in the rectum itself as a direct stimulant to peristalsis. In many of these cases a mild degree of intra-intestinal stimulation is found necessary for the upper bowel at first, and to meet this indication a laxative can be given, the dose of which, however, can be steadily diminished as the effects of the local treatment become evident, and finally be discontinued entirely.

I have treated a number of cases in this way and am glad to be able to report that the cure is not only complete but seems to be permanent.

Diagnosis of Gastric Ulcer.

BY J. L. ROTHROCK, M. D.,
Clinical Professor of Diseases of Women in the Medical Department of the University of Minnesota.
St. Paul, Minn.

Formerly the diagnosis of gastric ulcer was made with considerable reserve, and rarely before the occurrence of complications such as hemorrhage or perforation was a positive diagnosis ventured upon. Within the last decade, however, since the surgical aspect of ulcer of the stomach has received so much attention, much has been added to our knowledge of this subject by a more careful analysis of the symptoms supplemented by the occasional exploratory laparotomy in obscure cases, and which is now a common procedure. Just as in the case of gallstones, we no longer wait for the occurrence of jaundice, or in extra-uterine pregnancy for rupture of the tube with collapse from intra-peritoneal hemorrhage, before making a positive diagnosis. So in gastric ulcer a careful analysis of the symptoms will enable us to make a positive diagnosis in a large percentage of the cases long before the occurrence of dangerous complications.

Clinically, ulcers are divided into acute and chronic.

While all ulcers may be considered acute in the beginning if they do not heal spontaneously, as most acute ulcers do, they necessarily become chronic—each class presenting distinctive characteristic features.

Acute ulcer occurs most frequently in women, and before the age of thirty. While on the other hand chronic ulcer is a disease of middle or advanced life, and is more frequent in the male. According to Taylor's statistics, seventy per cent of acute ulcers are found in patients under thirty, while only seven per cent of chron-

ic ulcer was found before thirty. Recent investigations point to the probability that the location of the ulcer may have much to do in determining its character, and the explanation ventured of the great frequency of chronic ulcer in the pylorics is based on the mechanical irritation to which ulcers in that region are subjected, together with certain anatomical peculiarities.

Acute ulcer is furthermore seen in its most typical form in anemic and chlorotic girls.

The chief symptoms of ulcer are pain, vomiting and hematemesis. Pain is a fairly constant symptom. It is located in the epigastrium, and frequently radiates to the back. In the beginning it may not be constant, depending upon the character of the diet, and it is in this stage that ulcer is so often overlooked, the pain being regarded as cardialgia due to indigestion from hyperacidity of the gastric juice. The pain begins after the taking of food, and persists until the stomach empties itself. Older text-books laid diagnostic stress upon the relief from pain on taking of food. My own observation, however, leads me to believe that this is true only of liquids which act, perhaps, by diluting the very acid gastric juice.

Vomiting is rather frequent in acute ulcer, and at times is a very characteristic symptom. It occurs soon after the ingestion of food, and is due to the irritation occasioned by the presence of food in the stomach, the secretion of which is excited by the taking of food.

Vomiting of blood is of much more frequent occurrence in acute than in chronic ulcer, and, as a rule, is much more profuse, and may even reach dangerous proportions. The blood may be bright red if the hemorrhage is copious, or if mixed with stomach contents it is usually dark from the action of the gastric juice. Marked tenderness is usually present on deep pressure over the epigastrium.

In chronic ulcer pain is perhaps the most constant symptom, and rarely absent. It begins in from one to two hours after taking food, and persists until the stomach is empty; it may be very intense, and is usually paroxysmal in character. It is located in the epigastrium, and is deep-seated, radiating to the back. Vomiting is less common in chronic ulcer, with the exception of voluntary vomiting which patients frequently resort to in order to relieve their pain. Vomiting of blood is by no means common in chronic ulcer, and many patients suffer for years from this condition without having vomited blood.

The appetite in both forms of ulcer is normal or increased, and in this particular it differs from cancer, in which there is frequently loss of appetite. In both of these diseases there is frequently marked emaciation, but as has been well said, the patient with ulcer, while his appetite is unimpaired, is afraid to eat because of the pain he knows he will suffer if he indulges his appetite. While the patient with cancer has no desire to take food.

Constipation is almost always present. There is usually marked tenderness over the epigastrium, especially in the region of the pylorus.

Examination of the stomach contents will invariably show marked excess of free hydrochloric acid, which furnishes a very important differential diagnostic point between ulcer and cancer; in the latter it being usually greatly diminished or absent. A small percentage of cases, especially the acute group, appear to run a latent course, producing no symptoms until hemorrhage or perforation announce their presence. In further confirmation of this, instances in which scars are found in the stomach at autopsy without history of previous stomach trouble would point to the latent course ulcer may run. However, symptoms are soon forgotten, and many patients suffer the symptoms of indigestion without consulting a physician.

As illustrative of the usual course of ulcer the following typical cases are cited:

Miss E., aged nineteen, Norwegian servant, was first seen by the writer on the occasion of a hemorrhage. Patient had been in this country about a year. Six weeks previous she began to have pain in the epigastrium after eating. At first it was not constant, but only occurred after eating food difficult of digestion. Later, however, she suffered pain after each meal, which she described as burning and paroxysmal in character, and extend-

ing through to the back. Meanwhile her menstrual periods ceased, and, becoming alarmed, she consulted a physician who treated her for her anemia. She had never vomited until the day she had the hemorrhage. The hemorrhage consisted of about ten ounces of partially coagulated blood. The patient was pale, anemic, and had marked tenderness over the epigastrium. The diagnosis of ulcer was now plain, and under rest in bed and liquid diet for four weeks she rapidly regained her strength, and was able at the end of that time to take solid food without distress. A year later this patient reported that she had no further trouble.

The following history from a patient under observation presents the chief symptoms characteristic of chronic ulcer.

J. G., aged forty-five, states that he has suffered more or less from stomach troubles for the last five years. There was no history of previous illness, and patient had always been in the best of health until the onset of the present trouble.

The chief symptom of which this patient suffers is pain coming on an hour or two after eating. He first experiences a sense of fullness in the epigastrium, which is soon followed by pain which is paroxysmal in character located in the epigastrium, rather circumscribed and extending through to the back. The pain at times assumes intense proportions, probably due to spasm of the pylorus, and no relief can be had until the patient empties the stomach by vomiting, which he voluntarily does after drinking warm water. His appetite is good; at times voracious, though he fears to eat, knowing that he will suffer for it. Even water causes pain at times. He is much benefited by a prolonged course of liquid diet, but as soon as he returns to solid food his symptoms return. As a result he is considerably reduced in weight; wears an anxious and worn look. Examination shows marked tenderness over epigastrium, especially in the pyloric region. Examination of stomach contents shows very marked increase of free hydrochloric acid. Patient assures me he can only be comfortable if he confines himself almost exclusively to light liquid diet. He has never vomited blood.

This patient has since been operated upon, and an old ulcer with considerable infiltration was present at the borders with narrowing of the pylorus from cicatricial contraction.

[Written for the MEDICAL BRIEF.]

Treatment of Tic Douloureux.

BY J. H. FORD, M. D.,

Professor of General Surgery in the State College of Physicians and Surgeons; Chief Surgeon of the C. C. C. & St. L. Ry. Indianapolis, Ind.

The treatment of tic douloureux has been so unsatisfactory in the past that any new method which promises results will certainly be of interest to the general profession.

The operation of resection of nerves has been only temporary in its result, the nerves regenerating and the pain returning in from one to three months. Operative procedures further have usually included trephining of the bones of the face and the removal of large sections of the nerves as they emerge from their foramen, but these operations have been unsatisfactory.

The operation for removal of the gasserian ganglion is one of great difficulty, and the mortality has been exceedingly high, so that only those cases in which life has become unbearable will have recourse to it, and they should go to some surgeon who has made this operation a special study.

The method of treatment of tic douloureux by injections of osmic acid is not a new one, having been used by different men for some twenty or twenty-five years, though in desultory or haphazard fashion. The perfecting of the operation is probably due to Bennett, of London, who, some eight or nine years ago, took up the study of the operation, and has obtained results which look very promising. Previous to Bennett's investigation, the injections were made into the adjacent tissues, with the result of temporarily relieving the patient, but the pain usually returned in a very few weeks or a few months. Bennett's method is to make an incision over the foramens of exit of the supraorbital, infraorbital and mental

nerves, dissect out and pick up the nerve, and, with a fine-pointed hypodermic needle, inject from five to ten drops of a two per cent solution of osmic acid. He reports cases which he operated on eight or nine years ago, without a recurrence.

In 1903, Dr. John B. Murphy, of Chicago, took up the Bennett method for tic douloureux, and has written several exhaustive articles upon the subject. His methods are the same as those of Bennett, dissecting up the nerve and injecting the nerve trunk. The writer, following Murphy's and Bennett's method, has, so far, treated some sixteen cases with uniformly good results. The first case treated was in January, 1904. This was a man, sixty-two years old, who had been a sufferer for seventeen years, with the last three years of intense and excruciating pain, confining him to the house and to his room. He was unable to touch the lips with a spoon or a cup, was unable to touch the beard of the lower lip with his fingers without causing paroxysms of pain. The nerves had become so tender that the opening of a door near him would cause a paroxysm. He had been unable to feed himself for eight or nine months, except by dribbling some fluid food from a spoon held some two or three inches from his mouth, with his head thrown backward. I operated on this man, January 16, 1904, about four o'clock in the afternoon, under general anesthesia, dissecting out the nerve trunks and injecting them, passing my needle into the trunk, and as far into the foramen as was practicable, and divulsing the trunk of the nerves with the injection. That same evening he was able to drink out of a cup readily, and eat with a spoon fluid food, and has had no recurrence of the pain since, some twenty-one months. A letter from him, a few days ago, states that he has gained forty-five pounds in weight and was, apparently, in as good health as he had been in a number of years; was able to go out in all kinds of weather and perform any reasonable amount of physical labor.

In the total number of cases I have had but one recurrence. This was a case where an ulceration of the wisdom tooth took place, and the pain recurred, not in the face, but along the dental canal, and in the teeth of the lower jaw. This case was relieved by trephining the ramus of the lower jaw, resecting the nerve and thoroughly injecting and divulsing the proximal end. The writer would not like to say that these people are permanently cured, but the success so far obtained has been gratifying, and at least promises a fair amount of immediate relief. The operation is, usually, easily performed without disfigurement and without special inconvenience to the patient, with the exception of taking general anesthesia. In comparison with other methods of treatment, especially that of removal of the gasserian ganglion, it is the writer's opinion that this method of treatment should be tried before proceeding to more extensive operations. I have, invariably, told my patients that I could not promise them anything for the future, and could only tell from past cases what would probably be the result.

I think it is important, in making this operation, to see that the technique is carefully followed out, the mere cutting down on the nerve and injecting the surrounding tissues, and, probably, not getting the injection into the nerve proper, will not do. In such cases there will surely be a recurrence, because, while the nerve will be temporarily disabled, regeneration will soon set in, and the pain will return. The nerve must be destroyed, and I think osmic acid will accomplish this, owing to the oxidization of the surrounding tissues, and the setting up of a degeneration of the nerve from starvation. Murphy, in his experiments upon dogs and other animals, was satisfied that the osmic acid set up an ascending degeneration in the nerve, and I am inclined to believe that this is true. If the degeneration should proceed sufficiently far as to prevent regeneration occurring, then the relief is permanent, but unless the operation is carefully and thoroughly done, and the nerve trunk itself is paralyzed, and injection placed within the trunk itself, the operation will be a failure.

The incisions in the face, as a rule, need never be over one-half inch in length, as the nerves are superficial and easily found. I have never had any sloughing of the soft parts, nor any trou-

ble whatever with the wounds. Usually, the face is healed in from three to five days, the patient being out of bed, usually, on the third day, and ready to leave the hospital within a week.

I have had some experience with the injection of a one per cent solution of osmic acid in sciatic rheumatism. This experience occurred some ten or eleven years ago, and I have since, occasionally, followed this treatment in traumatic injuries to the sciatic nerve. Results have been fairly good, but I believe that it is not safe to inject any strong solution of osmic acid into a motor nerve for fear of loss of function. In the injections of one per cent solution of osmic acid in the sciatic nerve no incisions were made, but, commencing just behind the trochanter major, a hypodermic needle would be driven in the direction of the sciatic nerve, and about ten drops of the solution injected. The patient would be put in bed and kept in absolute rest. The third day after, dropping down the limb about one and one-half inches, another injection would be made. This would be continued until five or six injections were made, extending down almost to the bifurcation of the sciatic. As stated before, this method has not always been successful, but in some cases the relief has been prompt and the cure, apparently, permanent. My first case was eleven years ago, a man who had received a traumatism to the sciatic nerve, just behind the trochanter major. He had been treated by his local physicians, had gone to several watering places and rheumatic "cures," and had failed to find relief. After injection of the osmic acid, and three weeks' rest in bed, he was, apparently, permanently relieved, because I have had him under observation ever since and there has been no return of the disease.

Medical Testimony.

BY L. B. SAWYER, M. D.,
Professor of Medical Jurisprudence in the University Medical College.
Kansas City, Mo.

"Oh, wad some power the giftie gie us
To see oursel's as other see us!
It wad frae mony a blunder free us,
And foolish notion."
—Burns.

In this day of awakened American conscience, when, in the political world, men are exposing insurance graft; when railroad rebates are becoming a source of much investigation and attempted regulation; when the mammoth packing plants are coming in for a renovating; in fact, when long and continued abuses in so many lines of American life are being exposed, would it not be well for the medical profession to look to the abuses therein, and take some steps for their correction?

Much has been written in the medical world of the abuses by what is known as the professional witness or expert. He is almost as bad as he is painted, but, even in his prime, he is little in advance of the ordinary physician on the witness stand. Physicians, as a rule, are not untruthful; indeed, my experience has been that they are of as high a standard as men in any other walk of life, but many of them seem to have a peculiar conception of their duty when testifying in court. Unfortunately, the rule is that they take one side or the other of each case, and in their desire to convince the Court and jury of their views, go to great lengths in evading direct answers, and even greater in dodging the exact issue.

In a case in which I acted as the examiner, a surgeon who taught that branch of the science in one of our schools was the witness, and the following is an excerpt from his testimony.

The case was one in which a laborer had had his leg, at a point just above the ankle, caught between two twelve by twelve-inch timbers. One of these had rolled off a wagon and against his leg, bruising it, and several months after the accident his great toe was still flexed so that it turned directly down. The prin-

cipal question was whether or not the condition of the great toe was the result of the accident, and also as to the permanency of the injury.

Upon direct examination by the opposing counsel, the following is a part of the testimony:

Q. State whether or not, in your opinion, Doctor, there was any permanent results from that wound?

A. I don't see why there should be any. He claimed that his toes flexed, but I could not quite understand where the relation between that wound and that came in.

Q. Did you examine the toes?

A. Yes.

Q. How might the bend in his toes come?

A. Well, you see, you have distortion of the limbs, fingers, toes, etc., as the result of contraction of the body, as a rule, mostly; in this instance it would be the flexor, the flexor muscles; we have the flexors and the extensors that flex the fingers, toes and hands.

Q. Would this affect the toes in any way?

A. I couldn't see how it could.

Q. Do you say, then, in your opinion, there was no permanent injury resulting from this wound that you described?

After some objections and argument of counsel, the witness answered as follows:

A. I said before, I did not see where the connection came in, and why there should be any permanent injury from a slight skin wound.

On cross-examination by myself, the following is a reproduction of wisdom on the part of the witness:

Q. You said in your direct examination that the toes of that foot seemed flexed?

A. Yes.

Q. It was flexed? Doctor, what would cause that?

A. Well, we have those flexes in rheumatism, contraction of the muscle, various affections of that kind.

Q. Isn't it a fact that if the nerve supply of the muscles, the extensor muscles, that is the muscles that run along the tibia, if the nerve supply is cut off, that that will paralyze the extensor muscles, and will cause the toe to draw down?

A. Yes, sir.

Q. Isn't that the cause of that flexation, the nerve supply being cut off by reason of this bruised condition?

A. The nerve supply, the flexors, Doctor, would run on the outside, or the extensors would run on the outside of the leg, the flexors on the inside.

Q. Well, the limb was caught between two large timbers. Is it not probable that this bruised condition resulted in the destruction of the nerve that supplies the extensor muscles?

A. That might be a possibility; that, of course, would be conjectural, you know.

Q. Isn't it a strong probability?

A. Look, to-day you would arrive at that conclusion practically by an examination, you know.

Q. Well, you did not find any history in this case of rheumatism, did you?

A. No, sir.

Q. Then the probable cause of that is the destruction of the nerve leading to the muscle there?

A. May be an injury to the muscle.

Q. Well, if that is true, then, will this toe ever be straightened out; if that nerve is entirely destroyed, won't this toe remain crooked?

A. Well, I believe if that nerve is entirely destroyed you would have more of a contraction there of the toes.

Q. Can't you have destruction of part of a nerve and not the entire nerve?

A. That may be true, too, Doctor.

Q. Well, if the nerve is destroyed there, won't this toe always remain crooked?

A. Unless you get compensation there, and I am not sufficiently familiar with nervous diseases to tell you.

Q. How compensation; how can you get compensation when the nerve is entirely destroyed?

A. You can get a compensatory circulation there; I don't know how much compensation.

Q. Another branch of the nerve could divide and take root?

A. Yes, a nerve can be separated, Doctor, two inches, and you establish a connection between the nerve again.

Q. Now, if the only nerve to that muscle is destroyed, then you say that another nerve will branch out, could connect up with that muscle and provide for it?

A. No, I didn't say that, Doctor.

Q. What do you say?

A. I said that if there was a complete separation of the nerve that you could have the use of it, if it was an inch and a half or two inches long, sometimes by a contact, the same as an electrical contact.

Q. I understand, from pole to pole, you get a similar effect in there?

A. No, this nerve can be brought together, Doctor.

Q. By an operation?

A. Yes, sir. Now, I don't care about going into this question of nervous diseases, because I know very little about nerves; it is a specialty, you understand.

Q. You don't claim to be competent to say whether or not his toe will be crooked forever?

A. I would not say so.

Q. If this toe will be crooked forever then it would be permanently injured?

A. That depends upon how much difficulty it gives him in locomotion.

Q. Well, do you think a toe standing straight down this way (indicating) won't give him some trouble?

A. I don't know much about it, Doctor.

Shades of Standard Oil dodging! What manner of man is this; this expert who professed to possess knowledge? Stand up, juror, and tell me how the light has broken upon you, and how you are able to decide the question of injuries from such testimony.

In another case that I recall, the opposition doctor testified that the seat of intelligence in the brain of man was in the cerebellum. The injury was a fracture two inches above the eye and a little to the left of the median line. The company's physician, quick to perceive the trend of my cross-examination, placed the intelligence of man as far from the place of injury as possible, so that the mighty dollar, for which he was testifying, would be preserved.

Does the medical profession need the muck rake or shall its members investigate and try to see as others see, with the view in mind of correcting the abuses that are so patent to the world?

A physician recently said to me, "Expert testimony is a farce from any standpoint." This may be true, but no one has yet suggested a remedy that would appear to have much merit. Some have suggested a board of medical examiners to whom all legal disputes, in which a medical question is involved, should be referred. Other remedies, fully as impractical, have been suggested, but none has yet been offered that seems to meet the situation.

In the political world we find that publicity is being urged as the remedy in the management of great corporations in their internal affairs and their dealings with the public. This is resulting in much better and fairer treatment of the people generally on the part of the great corporations, and will soon result in more liberality on the part of the public toward them. In other words, the "square deal" is working out the great industrial problem, and it will work out all problems, whether they be of an industrial, economic or a medico-legal nature.

This remedy applied to the question of medical testimony should, in my opinion, be handled in this manner:

In every community where medical testimony is used to any great extent, there are well-established and active medical societies; let each such association have, as one of its principal standing committees, a committee on medical testimony. Let a fund be provided for the copying of medical evidence given by the members thereof, and other members of the profession. Let this committee furnish the most recent evidence obtainable to the association. It need not be used with a view of exposing the witness to ridicule, nor for criticism, but for the purpose of the education of the profession on the questions that are in litigation.

The result will be that physicians will be brought to know that the rash statements they may make to innocent (?) lawyers may be discussed by their brothers, and such statements as this, given by a prominent physician to me from the witness stand in answer to a question, will not be made:

Q. Doctor, tell the jury what part of the brain controls consciousness or intelligence?

A. The cerebellum.

Q. Where is the cerebellum located?

A. In the back part of the head.

Who will say that publicity will not check such practices, and is it not time for the profession to rise to the occasion and free itself, as a profession, from the odium of such acts on the part of its members?

[Written for the MEDICAL BRIEF.]

The Etiology and Diagnosis of Cancer.

BY J. FRANK CORBETT, M. D.,

Professor of Bacteriology Hamline University; Pathologist to City Hospital; Bacteriologist to Minneapolis Health Department. Minneapolis, Minn.

Since the days of Virchow, various attempts have been made to establish the parasitic origin of cancer. Plimmer described what he considered cancer parasites, and was the first to direct our attention to those structures commonly known as Plimmer's bodies. These are now looked upon as the result of secretory activity, and are common to all glandular structures. Busse, San Felice, Klein and Plimmer obtained torulæ, plants closely allied to yeast, from cancer. These for a time, confused with Plimmer's bodies and proclaimed to be the cause of cancer, were, later, shown to be one of the secondary infections occurring in neoplastic growths. The study of these organisms, therefore, did not clear the etiology of cancer, but gave us the pathology of a new condition, blastomycetic structures. We are still hoping for the discovery of a cancer parasite. Attempts have been made to grow these organisms on every conceivable variety of culture medium, and under every possible condition, using both natural and sterilized human fluids, under both artificial incubation and incubation of the living body. All such attempts have proven futile.

Quite recently Marx and Stickler have described certain invisible micro-organisms found in epithelioma contagiosum in birds. This is an epithelial tumor affecting the comb of chickens, and bears some relation to cancer. By using a Pasteur filter of non-glazed porcelain of such a degree of fineness as to exclude all common bacteria, they obtained a filtrate carrying these infectious elements. This filtrate to all bacteriological tests was sterile, yet contained the living infection, thus demonstrating epithelioma contagiosum to be due to an invisible micro-organism. It was thought, at first, that this might clear the etiology of cancer.

The same methods were applied by Jensen to rat carcinoma, the nearest analogue to human carcinoma. It was found that rat carcinoma did not contain any such infectious principle. W. R. Gaylord, in experimenting with mouse carcinoma, has been able to establish a certain immunity against cancer. This at once again suggested the parasitic origin of cancer and enormous possibilities in regard to a future antitoxin, but the results of Gaylord's experiments hardly warrant any such conclusion at the present time, and I will quote his closing statement in his last report: "Whatever the nature of this immunity, it does not appear to be cytolitic in its action. The histological picture indicating that the epithelial cells are, in some way, robbed of their power of distinct proliferation. An immune body is suggested as the cause." Molluscum contagiosum resembles beginning malignancy, but the etiology of molluscum contagiosum is as much an enigma as is that of cancer. Coccidium infection presents certain phases of epithelial proliferation that suggest the beginning of cancer. When we stop to consider the entire history of this condition, we find that coccidium produces the same degree of epithelial proliferation that we get in many other infections; that this proliferation does not continue, but is rapidly followed by a retrograde process, resulting in desquamation and degeneration.

J. N. Hyde says the skin is somewhat hypersensitive to light, and, as a result, we may have a train of sequences beginning with hyperemia and ending in cancer. In proof of this, he cites Xeroderma pigmentosum and cancer resulting from X-ray burns.

The weight of experimental evidence, at the present time, tends to show that cancer is not an infection, but a riotous proliferation of cells, incited by some stimulation, or free from their natural restraint; therefore, at the present time the treatment of cancer is purely surgical.

The successful cures at the present time have been limited to cancers on or near the surface. In the surgical treatment of early cancer on the surface much has been accomplished. The reason we say little has been done in cancer of the stomach, and to a lesser extent cancer of the breast, is due to the extreme difficulty of making an early diagnosis. The surgical technique of gastrectomy in the hands of Robson, Moynihan and Mayo has approached so nearly to the ideal that little more can be expected in this direction. However, the great problem confronting us is one of diagnosis.

The chemical and bacteriological examination of stomach contents, so highly lauded by our Vienna confreres, do not often enable a diagnosis to be made sufficiently early to be of any practical value. The results of these examinations, considered without strong clinical backing, often lead to grave errors in diagnosis; therefore, some other procedure must be adopted to reach a sufficiently early diagnosis. At the present time early exploration affords the only possibility. When we consider the fact that at the present time, the most of the cures of carcinoma by gastrectomy have resulted from exploratory examination made for some other condition, the importance of this is further emphasized. The problem is not entirely solved when we have the abdomen opened. We may encounter a callous ulcer of the stomach that, to all external appearances, is identical with carcinomatous ulcer. From a series of photographs in my possession, we might conclude that the difference between a malignant and non-malignant chronic ulcer was *nil*. On close inspection, however, we find that the base and edges of the malignant ulcer are generally smooth and densely infiltrated, while the same areas in a non-malignant ulcer are more or less ragged and eroded. Further, in malignancy, the walls of the stomach are usually thickened. In chronic ulcer the walls of the stomach are ordinarily thin. These differences do not always enable a diagnosis to be made; in that case a portion of the ulcer should be removed and examined by frozen section method during the operation; a positive diagnosis may be made in this manner in from six to ten minutes, and the operation proceed without material loss of time.

Malignancy lies in wait where we least expect. For instance, we may have a malignant appendix that differs in no outward respect from a thousand other non-malignant appendices. And, if routine pathological examinations were made of all appendices removed it would probably be found that a larger number were malignant than we can claim at the present time. As a notable illustration of this I quote the case of Dr. Harper. Had there been a pathological examination, it is probable that his life might have been saved.

In no place is the immediate pathological examination of tissues of more importance than in tumors of the breast. I have a remarkable series of cases illustrating this. Many of them, apparently benign, were, in fact, malignant; others apparently malignant, were, in reality, benign. The frozen sections and microscopical examination enabled a diagnosis to be made in all of these cases, with the results that some of the patients were operated upon early enough to obtain a complete cure, and others were saved an extensive and unnecessary operation.

Operations for Traumatic Epilepsy, With Report of a Case.

BY W. O. ROBERTS, M. D.,

Professor of Principles and Practice of Surgery and Clinical Surgery in the University of Louisville.
Louisville, Ky.

Epilepsy, following head injuries, may be divided into three classes, viz., those which are due to a peripheral nerve lesion in the scalp; those due to changes in the bones or dura at the site of injury or fracture of the skull, or adhesions of the dura to the bone; those due to injuries of the brain itself.

In the treatment of head injuries it must always be borne in mind that there are possible sequela, which are not apt to occur, however, except in cases of fracture.

Before the aseptic era there was a difference of opinion among surgeons as to the advisability of elevating depressed bone, which was not giving rise to symptoms. Now, however, there is practically unanimity of opinion in favor of it. Those opposed to the elevation of the depressed bone contended that it would be time enough to elevate it when the sequela appeared. Those who favored the operation contended it was better to use every means to prevent sequela, as operations for their cure were not very promising.

Great good may be expected from operative interference in traumatic epilepsy when it is undertaken early; but if it is deferred until the "habit" has become established, the results are very unsatisfactory.

The only cases in my own practice where cures were effected by operation have been those that were undertaken early. Still, I advise that the operation be undertaken, even in the old cases, as I believe it gives the only chance, slight as it may be, of relief. The operation of trephining, in itself, when done under a strict technique, is attended with very little risk, except in the neighborhood of one of the venous sinuses. When a sinus is opened there will be, of course, great hemorrhage. The best method of controlling this is by gauze packing. Therefore, before beginning the operation, be sure to have strips of gauze in readiness. It is astonishing how much gauze can be used in these cases without producing pressure symptoms. It is, of course, of vital importance to make a note of the strips used, and have their ends hanging out of the wound, so that there can be no possibility of a piece being overlooked. The removal of the gauze should begin at forty-eight hours. In order to guard against recurrence of hemorrhage, remove at each dressing only that portion of the gauze which is not adherent. It will likely take several days for it all to come away.

Case 1.—This patient was brought to me by Dr. J. K. F., with the following history: Age, thirty-five; married; occupation, cabinet maker; previous to four years ago his health had been good. Family history excellent. About four years ago this patient received a severe injury of the head, caused by a blow from a flying piece of timber while in his shop. He was knocked down by the force of the projecting timber and afterwards became so dizzy and nauseated that he was unable to continue his work. Following this he had headache, and, finally, the pain in his head became so severe that he had to go to bed. After suffering for nineteen weeks he was operated upon by Dr. J. M. Holloway; the operation consisted of raising a horseshoe flap of the scalp at the site of injury. About ten days after the operation the man returned to work. While his headaches were benefited, they did not entirely disappear, and, two years later, he began to have attacks of unconsciousness. These gradually became more frequent and violent. A few days before the patient came to the hospital, Dr. Freeman was called to the factory to see him, and found him in a convulsion. The Doctor stated that it was a typical epileptic seizure. After the convulsion had passed away, Dr. Freeman, in examining the man's head, made some pressure with his finger at the site of the old injury, and this brought on another spasm. The tender spot was one and one-half inches posterior to the external angular process, and one and three-quarter inches above the zygoma. At this point I exposed the bone by horseshoe incision, three and one-half inches broad. A large trephine was used. The button of bone removed was unusually thin and was adherent to the dura, which was found to be very vascular and thickened. In the removal of the button the anterior branch of the middle meningeal artery was divided. The hemorrhage, which was rather profuse, was controlled by pressure with strips of gauze, the ends of which were brought out at the angle of the wound. At the end of forty-eight hours, the dressings were changed, and this gauze packing was removed without any recurrence of hemorrhage. The patient has gotten along without any untoward symptom, and the wound is about healed. It is not only possible, but probable, that the thickened and adherent dura has been the cause of the epilepsy, and, if so, the operation will relieve him.

706 Chestnut Street.

[Written for the MEDICAL BRIEF.]

Diagnosis.

BY B. H. OGDEN, A. M., M. D.,

Professor of Obstetrics in the Homeopathic Medical College of the University of Minnesota.
St. Paul, Minn.

"The man who knows not that he knows not aught
He is a fool; no light shall ever reach him.
Who knows he knows not, and would fain be taught—
He is but simple; take thou him and teach him.
But whose knowing, knows not that he knows—
He is asleep; go thou to him and wake him.
The truly wise both knows and knows he knows—
Cleave thou to him and never more forsake him." —(*London Spectator.*

To be a skillful diagnostician is one of the most essential qualifications of a good physician or surgeon, and a proper understanding of the relationship of the diagnosis of disease or disturbed physical conditions, to their curative treatment, is imperative, not only to secure the best results for the individual patient, but to obtain any intelligent advancement in the treatment of disease. We do not merely want to know that certain symptoms have disappeared under the action of a remedy, but to know upon what basis they rest, for inasmuch as a given symptom or group of symptoms may arise from extremely varied lesions, can a certain remedy always remove them, irrespective of their causes? If not, upon what do the symptoms depend when a remedy can and does remove them? Is the physician competent to prescribe in accordance with the law of similars who has no knowledge of the significance of symptoms, who does not know that a given pain of sensation may be due to a variety of causes; who, when he has seen symptoms disappear under treatment, does not know whether they depended upon some grave hepatic lesion or some functional and ephemeral disturbance, and, consequently, can have no idea as to the role played by the remedy prescribed, in the removal of the symptoms? When a man who claims that diagnosis is of no practical value reports an almost miraculous cure with one dose of the fifty m. or ten drops of the tincture, how much credence is due his statement, how much right has it to a place in clinical homeopathy. Is a man holding such views in regard to diagnosis liable to be a skillful diagnostician? Have we, can we have, from such a source reliable evidence as to the curative power or sphere of a remedy? Is it not well, in addition to the oft-repeated question of "What cured?" to inquire "What was cured?" I have no sympathy with those who maintain that, for therapeutic purposes, a diagnosis is unnecessary, and prefer to select their remedy before having made this most important study of their case, nor can I join in the pleasure of those who "rejoice exceedingly" over a correct diagnosis, but do not deduce therefrom a method of treatment which shall cure or benefit the patient. The longer I practice medicine the more I am convinced that the "dear public" cares little or nothing for methods, provided only their cure is secured quickly, safely and pleasantly. They do not care whether this is brought about by the use of a large or small pill, or none at all. They do insist, however, that what is done be safely done and are quick to condemn any errors of commission or omission; they are unwilling to take medicine *ad nauseam* for conditions which can be relieved as well or better by pleasanter methods, or, on the other hand, to use what they term easy-going treatment, when more heroic is required. In short, there is an increasing demand for more than average intelligence and skill in physicians.

When sickness enters a household it is a matter of no small moment that a proper physician be selected, one who is not given to fads or committed to theories, one who is not always introducing new things or too slow in giving up the old, one who does not see in every simple disturbance the beginning of some terrible disorder, which he hopes to break up, or who, on the other hand, examines carelessly, and thus fails to recognize really serious disorders. He must be a man of strong principles and good judgment, thoroughly informed upon all methods of diagnosis and treatment, able to observe correctly and form logical conclusions, for upon these often hangs the issue of life and death. Medicine is not now and, perhaps, never will become an exact sci-

ence. "Two and two do not always make four in the reactions of the human body." Personal idiosyncrasies must be considered. What is one man's food may be another's poison. The same symptoms may result from widely different causes; there is, therefore, great danger that the physician's conclusions may be incorrect, because, in his syllogisms, he has constructed wrong premises. He must often be compelled to reason from probabilities. Here is the field for good judgment, and is very often the keystone of success or failure. As Butler, in his excellent work on diagnosis, says: "To, study and compare; to approach a case with a mind open to impressions and without preconceived or fixed ideas as to its nature based upon previous hearsay; to review and balance the evidence, from time to time, in the course of the disease; to question one's self—is there any other condition or disease which better explains these conditions than that which I have already assigned? These and other habits of thought make the difference between the man who sees without learning and he who learns by seeing." Some one has well said, "the safeguard of any truth lies in the standing invitation to the world to prove it false." So the safeguard against making or maintaining an error in diagnosis will be found in one's willingness to review and weigh evidence impartially, and change his opinion if need be.

What are some of the reasons why I attach so much importance to diagnosis?

In the first place, and I name it first because I believe it the most important, a correct diagnosis is necessary that we may be enabled to select from the various methods of treatment that which is best adapted to the cure of the patient or, perhaps, to combine measures which will give relief. The day is passed when any one system of cure is to be universally applicable to all forms of human ailment. "If this be treason, then make the most of it." The sooner the physician understands and makes the laity understand that in curing the sick the giving of drugs does not constitute all or the greater part of his duty, but that in properly selected cases drugs are essential, the sooner will he help to do away with the present disagreements among those who are treating the sick, and the too frequent distrust of the profession by the laity.

A proper differential diagnosis is essential at the very beginning, in order to understand the meaning of symptoms. A patient suffering from melancholia, with suicidal tendencies, may be simply suffering from malnutrition, and a proper administration of nourishment will restore his health; or his nervous system may be poisoned by a process of acute infection from long-retained fecal masses and a thorough house-cleaning is needed. Over-anxiousness and useless worry may have long been a habit, which a wise counsellor may overcome by suggestion. A sedentary life may be the prime causative factor, when massage and methods of manipulation will bring the best result. The sensitive, nervous system may have become so disordered that some drug as aurum, prescribed carefully from the homeopathic indications, may be necessary to establish a cure. Any one, or perhaps all of these methods, may be required in a given case. Shall we permit the undoubted value of aurum in such a mental state to be discredited, because we have failed to realize, also, the necessity of a cathartic? Or shall we, for one moment, permit any class of physicians to refuse us the right to use a cathartic because we also believe in the efficacy of aurum, prescribed on homeopathic principles?

Nothing makes me so righteously indignant as the slurring remarks made against the homeopathic physician who uses, occasionally, a cathartic or an opiate or an antacid, and I have been more than pleased to note how many of the profession have recognized our classical defintion of a homeopathic physician.

There are certain limitations to any method of treatment, certain lines within which all goes well, outside of which all is wrong. You can not cure pneumonia with a knife, you can not safely open an abscess with a drug. Shall the knife, therefore, rail at the drug or the drug at the knife?

The present era of medicine has been called anarchistic. Certainly it is an era of rebellion against the arrogant domination and assumption of all knowledge, which has too often characterized medi-

cal men. The extremes of this rebellion have resulted in fads, whose motto is "away with medicine, down with the physician." But, out of all this confusion, good to the human race will result, and it will come through a more careful classification and diagnosis of human disorders, so that each case will be individualized with reference to the kind of treatment best adapted to its cure.

Homeopathy has taught the world the grand lesson of individualizing different patients suffering from a common disease. but we must now go a step further, and individualize deviations from health, with reference to selecting the best method of restoring to health. Before considering at all the question of medication, or the form of treatment of any given case, the physician must determine as fully and as exhaustively as possible, not only in what respect his patient differs from normal, but why this difference exists. What are the abnormal conditions and what has produced them? This makes the thorough understanding of the etiology of disease an essential element of its diagnosis. Hahnemann recognized this, and emphatically stated that whenever possible the cause of disease should be removed. It was really this thought which led him to develop his theory of chronic diseases, *i. e.*, the endeavor to find an ulterior cause and remove it, and so he could, by a different class of remedies, overcome certain dyscrasias which served as an underlying cause of disease. With our later-day knowledge and ever-increasing information concerning the causes of disease, *tolle causam* has a far wider significance and importance than even in the days of Hahnemann, and makes necessary a much wider field of resource in treatment of disease than in his day. The germ theory of the origin of certain diseases, the poisoning of the system by various toxins, have naturally and most logically developed the use of antiseptics and antitoxins, and he who uses them is not following after the fleshpots of Egypt, as some have said, but rather is he following to its logical conclusion the advice of that master mind when he emphasized so strongly *tolle causam*. Remove the cause.

Very much of our recent advance in surgery is but the exponent of this principle, remove the cause. Peritonitis, as an idiopathic disease, is almost out of date, and is not now accepted by health officers as a cause of death unless qualified, because it is so generally recognized to be secondary to some other condition, such as appendicitis, perforation of the intestines, pus tubes, ectopic gestation, in which the removal of the cause means surgery. Thus, again is brought before us the extreme importance of the correct diagnosis of disease and its cause, that medical and surgical cases may be correctly differentiated. Whichever way you turn the question of diagnosis confronts you, and what a sense of comfort and assurance belongs to him who knows his ground, compared with him who only guesses.

What a misfortune it is, what a discredit comes to our profession when a child is treated for weeks or months for a supposed pneumonia, when the condition is an empyema, which can only be cured by resection of a rib and free drainage. Or, when a diagnosis of grip is made, when a more thorough examination, including blood analysis, would easily demonstrate typhoid fever. Perhaps, in the latter case, a good symptomatic prescriber would select the proper remedy, but what a small part of the treatment, as a whole, is represented by the giving of the correct remedy in such a case. Besides the necessity of determining what form of treatment is best adapted to a given case, a correct diagnosis is necessary that we may select the proper remedy from the totality of the symptoms.

Totality of symptoms are words glibly spoken, but when seriously and earnestly considered, they mean a great deal. Besides the subjective symptoms, detailed by the patient, there is that large and important class of symptoms termed objective, which are only discovered by a careful physical examination, and, finally, pathological conditions, tissue changes and derangement of the function of organs, as revealed by the microscope and test-tube; all of these go to make up the totality of the symptoms and a knowledge of them is important if you would make the best prescription. Not a day passes,

in my experience, that I do not find a correct diagnosis essential, the most essential factor in enabling me to make a correct prescription.

Again, diagnosis is necessary to enable one to anticipate and prevent disease or serious complications. In no place is this more evident than in the branch it is my privilege to teach at the State University. Because of a more thorough study of the methods of diagnosis and the relation of diagnosis to treatment, a new word has been applied to this method of dealing with abnormal conditions. Election in opposition to Compulsion. Because of the knowledge of renal insufficiency, we are not so often compelled to treat puerperal convulsions, but we elect its preventive treatment. By means of knowledge gained from pelvimetry, we are not compelled to resort to the major operations resulting from a contracted pelvis, but elect to produce a premature labor; or, if the case is first seen too late for this, we do not wait until the exigencies of the case force upon us a midnight operation, with poor surroundings and assistants, and upon a patient already exhausted, but we anticipate this necessity and elect our own favorable time and surroundings upon a patient carefully prepared, with far better chances of a favorable result.

Extending this same idea to general medicine, a correct diagnosis and consequent knowledge of the history of the disease; an understanding of the different temperaments and their morbific tenddencies, as detailed by Professor Comstock, will enable the physician to anticipate and prevent many serious complications and sequelæ. In all contagious and infectious diseases the necessity of diagnosis and prevention is so obvious that no remarks upon this line are necessary, and those who ignore this necessity are so plainly derelict in duty that even the "wayfaring man, though a fool," condemns them. Even Mrs. Eddy has been compelled by public sentiment to issue a "bull," forbidding healers to treat contagious diseases, thus recognizing their existence and the necessity of diagnostic ability.

I have briefly mentioned some of the reasons why I attach so much importance to diagnosis. I wish, in closing the paper, to refer briefly to some of the methods of making a diagnosis. The question now is not why, but how, diagnosticate? To answer this in full is to write a book. In my student days, "Da Costa on Diagnosis" was a well-thumbed book, but the subject has been so much enlarged since his day, and so many new and important discoveries in the line of laboratory methods have been made, that a recent work is a necessity. Recently, a well-informed person, but one inclined to magnify the weakness of the poor human mind, said to me: "A physician's diagnosis is nothing but a guess, liable to be good or bad." I rebel against such a statement. Diagnosis is not a guess, and such a statement and such a sentiment, I am sorry to admit it is fairly common, is false, all the more so and misleading because it is a distortion of a partial truth. It is true that complex conditions may exist which render a diagnosis, at first, impossible; and the physician is often unavoidably puzzled, but puzzles are not peculiar to the medical profession, the philosopher, the chemist, the scientist, the theologian, the business man, the mechanic, have similar difficulties. Who does not have his puzzle? The inability to make an absolute diagnosis in certain cases does not make all diagnoses mere guesswork, rather does it serve to emphasize its scientific accuracy. It is only he who is always cocksure of his diagnosis who does the guessing. Unfortunately, too many have yielded to the unreasoning demands of their patients that the nature of their malady should be named at once and have, therefore, fallen into error. We need still to sit at the feet of that greatest of ancient, if not of all philosophers, Socrates, and learn that the beginning of wisdom is the knowledge that we do not know. Who does not know and knows that he knows not, will learn, and is in the direct line of advancement to the unassailable position of him who knows that he knows. That, naturally, brings me to consider my first subdivision:

How to Make a Diagnosis—viz., make your mental attitude toward any subject of investigation one free from prejudice, receptive, logical. This judicial mind is a natural gift to some, others obtain it through training and education, and a

few seem incapable of its development. It is a pity that any of this latter class should enter the medical ranks. Occasionally, we are asked of what direct benefit to a physician is the time spent in the study of natural philosophy, geometry, trigonometry, and higher mathematics, analytical chemistry, logic, philosophy of history, political economy and similar studies? The answer is plain. These are the best known methods of teaching the mind the habit of accurate observation and of logical deductions therefrom. Before one is fitted even to begin the study of medicine, such an education is necessary. The more we study, and particularly the longer we practice medicine, the more alert our perceptions become, hence the saying, "An old practitioner for a diagnosis." The mental attitude of the expert detective following a clew, and of the physician in making a diagnosis. are identical. This is admirably illustrated in some of Dr. Conan Doyle's stories. How simple the snarl of symptoms or circumstances becomes when analyzed by the master mind! How confusing and impossible of solution for him if he allows some symptom or circumstance to become unduly magnified. We must know the relations of symptoms to each other in the order of cause and effect. It is folly to suppose that every condition, whether better or worse, which follows the administration of a drug, or of any other method of treatment, is the direct result thereof. Very many of our clinical reports are absolutely worthless because the mind of the reporter was never trained in the study of evidences. This is well illustrated by those who maintain that the paralysis which sometimes follows the use of antitoxin in diphtheria, is caused by the antitoxin, although before antitoxin was discovered or dreamed of, post-diphtheritic paralysis was of common occurrence. A patient of mine was suffering the agonizing pain of a middle-ear abscess formation. I urged the use of some opiate and prescribed the same, but, instead of taking it, a Christian Scientist was called. At first but little relief was obtained, but, *mirable dictu*, in four hours the pain suddenly left. Such was the story told me, and great was the Christian Scientist. Nothing was thought of the coincidence that the ear began to discharge pus, or of the more deplorable continuance of a stinking discharge, lasting three or four months, and the final destruction of the membrana tympani and the ossicles, with impaired hearing. Oh, no; this was the continuing effect of the scientist treatment in ridding the system of its impurities! Rdiculous in the extreme, and yet I have seen a report of a case of peritonsillar abscess very quickly relieved of swelling and soreness as of a boil, by a dose of medicine when the real benefit resulted from the spontaneous bursting of the abscess.

Let me repeat, the first essential in making a diagnosis is to have a well-balanced mind; then, with all the mental acumen he can muster, the physician proceeds to the details of obtaining the evidence upon which to base a diagnosis. First, the patient is asked to tell his story. Do not ask what is the matter, but say, "Now tell me all about yourself, in what way you feel ill, how and when your trouble began, and what have been the various symptoms, in their order." Then listen attentively to the recital, without making too many interruptions. Let the patient tell his story. Meanwhile, jot down on paper or in your mind points which need further elucidation. Do not allow a patient to say his kidneys pain him, or that he has liver disease, or use any of the set terms of medicine, without pointing out just what he means by them. Do not allow a patient to make your diagnosis, but do not ignore his theories, for he has, doubtless, given his trouble much thought, and they may be worth listening to. In this recital you are looking for facts, and after the patient has finished, you then put him through as rigid and keen an examination as ever befell a witness on the stand, that you may determine the relative importance of the facts elucidated, and their absolute accuracy. The patient may be too ill or too young to state his case, but you must depend upon the statement of others. In such cases your cross-examination should be all the more rigid for you do not know how accurate such observers are. Lastly, in obtaining evidence make your own observations and remember that a poor observer will never make a good diagnos-

tician, either of disease or the remedy for its cure. Under observation I include all the facts which can be elicited by the general appearance of the patient, in points of nutrition, diathesis, cachexia, posture and gait, appearance, color of skin and tongue and mucous membrane of the nose, mouth and throat, temperature and pulse, and all that is to be obtained by a thorough physical examination of all the organs of the body. Much of this is routine, and some of it in a given case may not be necessary; the time it takes is great, and after the physician becomes very busy he can not go over it so thoroughly, but by that time he should have become sufficiently acute to pick out those organs which need special examination. In this we need to be extremely cautious or every little while we will be discovered making a mistake, not because we do not know, but because we have not looked. There are certain routine methods of examination which should be followed, *e. g.*, always examine the throat of a child with fever. Besides the ordinary physical examination, we should avail ourselves of the knowledge to be obtained through modern laboratory methods, notably a thorough chemical and microscopic examination of the urine or a clinical examination of the blood, erythrocytes and leucocytes, their shape and size, the amount of hemoglobin, the plasmodium of malaria, the serum test of the Widal reaction in typhoid fever; also, the bacteriological examination of the sputum and secretions of the throat and the chemical examination of the stomach contents, after a test meal upon an empty stomach. The examination of the character of fluids obtained through diagnostic procedure. These and other methods which I have not the space to mention, show you how broad is the modern field for obtaining facts or evidence of disease. Having obtained all the evidence or facts, accurately, we are then ready to group them and make them into premises of a logical syllogism, and form our conclusions. In order to do this correctly, we must know thoroughly the meaning of the various facts. This is a study in itself and very important. The diagnostic value of the character and locality of pain is worth weeks of study; the meaning of dizziness, headache, vomiting, the amount and character of fever; the import of a chill, whether severe, prolonged, or simply chilliness; the meaning of the presence or absence of vocal resonance, vocal fremitus, and so *ad infinitum*.

In conclusion, let me say that while I can not emphasize too strongly, the value of diagnosis, it is not the physician's *summum bonum*, it is but the means to an end, viz., the prevention of disease, the relief of suffering, and the cure of the sick. We should give no ground for justification for those who would belittle diagnosis and claim that the diagnostician is never more pleased than when the *post-mortem* findings verify his statements.

It is true that Hahnemann and his contemporaries made brilliant cures without all this later-day knowledge, but how much more could have been accomplished by such minds had the diagnostic aids of to-day been theirs to command. Bigotry can never promote science and truth, and without these there can be no advance in medicine. To be able to discern truth and follow its teaching, this is the mark of mental balance, which I think is best exemplified by him who adds to his knowledge of medicine a special knowledge of homeopathic therapeutics. All that belongs to the science of medicine is his by inheritance, by tradition, by right.

Nutrition.

BY RICHARD E. MCVEY, M. D.,
Professor of Skin and Venereal Diseases and Clinical Medicine in the Kansas Medical College.
Topeka, Kan.

The cell is the unit of animal and vegetable organizations, and nutrition is for the repair and maintenance of the cells during organic life. Nutrition and life are very closely associated. Life implies intelligence, so that behind all organized life there is an infinite intelligence which guides and directs both physical and chemical forces, as is manifested in the phenomena of life.

Protoplasm is the first form of living matter known; it is found in the sea and on the land. In the sea it produces all the forms of aquatic life; on the land all

the forms of life are evolved from it, from the ameba to man. In the vegetable it is a slimy, semi-fluid, cellular substance; in man it is the same semi-fluid substance. The laws of nutrition are the same in the plant and in the animal. The plant cell liberates force, as does the animal cell, and, like it, produces carbonic acid, but spends much less energy, and the phenomena predominant in it are those of assimilation. The plant seizes upon the carbonic acid and nitrogen as found in the air and soil, and unites them with water, thereby producing a nutritive molecule—principally a carbohydrate—which furnishes the animal with its nutrition; but, for the reduction of this nutritive molecule, or carbohydrate into a medium which can be appropriated as a nutriment for the cells of the animal tissues, it must undergo many physical and chemical changes.

In a unicellular being nutrition consists of four acts:

1. Endosmosis and the absorption of nutritive material.
2. A chemical change in the nutritive molecule absorbed by the cell.
3. A synthesis, a repair of waste, or tissue building.
4. Exosmosis of waste products.

All nutritive substances must be in a soluble or fluid condition to be absorbed by the walls of the tissues. In the higher forms of animal life an artifice is necessary for the solution of nutritive substances. The blood and lymph are the great media of exchange between the cells of the body and its food environment.

For the reduction of nutritive substances before their appropriation by the cells of the tissues, a whole system of glands and tubes is provided, with their ferments, which produce the necessary physical and chemical changes for cell nutrition. Each gland has a separate function, peculiar to itself, in the transformation of the various kinds of food elements. Some of these glands produce hydration and others dehydration, for the purpose of dialyzation by the tissues.

The solution of nutritive substances takes place in the intestinal canal. The secretions of the glands of the intestinal tube dilute and dissolve all the food elements. If left in this dilute condition they would pass through the tissues too rapidly, but as they pass through the intestinal walls all of the food products are dehydrated. The starches are saccharified; the albumins are peptonized, and the fats are partly emulsified, and partly decomposed into fatty acids and glycerine. After this dehydration, the peptones form new albumins, and the decomposed fats are recombined in the lymphatics, and especially in the liver, which arrests the fatty acids, a part of the peptones, and the sugar. Glucose is dehydrated and forms glycogen, which accumulates in large quantities in the various tissues, and especially in the muscles. The albuminous substances, after passing through the intestinal walls, enter the blood as serum albumin.

A typical cell is surrounded by a homogenous membrane, which contains a large amount of lymph, closely associated with the ultimate molecule of which the membrane is made up. This cell-membrane is a porous partition whose pores are filled with lymph, and which separates the cell contents from the surrounding media. The cell contents may be gaseous or fluid-like, more or less like the solids. The passage of nutritives from the exterior to the interior of the cell must be through this porous partition, and the nutritive elements must be so transformed as to be similar to the cell contents. The cells all have a selective affinity, and select from the pabulum those elements which are demanded for their repair and proliferation. For the perfect metabolism of food products a certain amount of oxygen must also enter the cell. In this metabolism a certain amount of energy is liberated, and there is also a certain amount of rejected or waste material. The chemical process concerned in the assimilation of food products by the cells, results in the formation of carbon dioxide, urea and creatin, and other crystalline bodies, which are no longer of use, and which must be removed from the cells. It has been stated that it is possible to find out, approximately, the nutritive state of a man by the amount of his excreta. "An adult voids, in twenty-four hours, two hundred and fifty grams of carbon and eighteen grams of nitrogen. He must ingest, therefore, each day, elements which will furnish the

same quantity of these two substances. He will obtain the eighteen grams of nitrogen by consuming five hundred grams of meat, but for the two hundred and fifty grams of carbon he will need two kilograms of meat. These figures show the necessity of a mixed alimentation. If vegetables are added to the diet, the ratio of maintenance is obtained by giving five parts of carbohydrates to one part of nitrogenous matter" (Rogers). When these proportions in alimentation are not observed, disturbances break out. Poor food in quality and quantity leads to the development of disease. If we take the carbohydrates in excess, too much glucose is absorbed. The cells of the tissues are unable to oxidize it all, and some of it may pass into the urine, and we have a temporary glycosuria. If the nitrogenous substances are in excess, they may be absorbed, but do not undergo the proper transformation into urea and other excrementitious substances.

Man is largely composed of water. A certain amount of water, or lymph, must always be present in the cells of the tissues for the purpose of perfect hydration of waste products. If these products are not hydrated they are not dialyzable, and when discharged into the tissues they set up irritation until such time as their hydration and dialyzation take place.

When there is a normal balance between the income and the outgo, the serum of the blood is not very toxic, nevertheless the tissues themselves and the serum are always more or less toxic. There is a constant variation between the toxins of the blood and those of the urine. When the toxins are diminished in the urine they are increased by accumulation in the serum. Ten different toxins have been found in the urine. The principal toxin is mineral potash, which, when retained in the serum, has a depressing effect upon the heart. There is also a convulsive toxin, which often lies behind uremia and epilepsy. Whether the resulting eclampsia will be fatal or not depends upon the amount of toxin in the serum, which may be estimated by injecting the serum of the affected person into the veins of a rabbit. The amount of the serum required to kill the rabbit will determine the toxicity. Ten c. c. of human serum (normal) are sufficient to kill one kilogram of rabbit (Roger). In persons who have weak or enfeebled action of the heart, foods containing large quantities of potash salts should be interdicted.

In pneumonia the toxicity of the urine is diminished, but on convalescence it is increased, which seems to indicate that the poison of pneumonia is eliminated through the kidney, and that the irritating element in the lung has been an undialyzable nitrogenous one. The fact of its elimination through the kidney is evidence of its nitrogenous character.

There are certain glands whose functions are probably the neutralization of toxins originating in the various tissues of the body, and chief among these may be mentioned the liver, the thyroid gland, and the suprarenal capsules. It is in the liver that the final dialyzation of the nitrogenous substances of disassimilation are transformed into urea, and the carbohydrates are rendered dialyzable. The function of the thyroid gland is said to be to regulate the circulation of the blood through the brain, and to neutralize the toxins coming from the brain. If the thyroid gland and the parathyroids are involved in disease, we have mental or cerebral apathy, myxodema and cretinism. The suprarenal capsules perform a very important function in nutrition. They neutralize the albuminoid toxins coming from the muscular system. In disease of these glands we have Addison's disease and melanemia, and other forms of pigmentation.

While nature has made provision for the neutralization and elimination of toxins formed within the organism, there is no special provision for the removal of toxins formed from micro-organisms, and this is especially true of the specific micro-organisms. Either the germs themselves, or their toxins, remain permanently, as seem to be the case in syphilis and tuberculosis. It may be, however, that the leucocytes devour some micro-organism and transform them into toxins which can be removed through the normal channels, but in the exanthemata, immunity is established through retention, permanently in the tissues of the toxins in the latent form.

Dr. Bouchard established that the urine contains numerous toxic substances, to which three sources may be assigned—alimentation, gastro-intestinal fermentation, and disassimilation. The digestive canal represents the principal apparatus for the production of auto-intoxication. The fermentation occurring there is exaggerated intoxication, under a great many circumstances. In other cases the toxins produced are not eliminated. In an attack of indigestion or dyspepsia an auto-intoxication is induced, attended by numerous disturbances, such as headache, weakness and general exhaustion.

We can recognize the power of the liver by several procedures. The hepatic cells are united, interdependent; when one is disturbed, the others are affected at the same time, and the liver fails to arrest the poisons; it no longer elaborates the bile, it no longer acts in a normal manner, it no longer acts on nitrogenous matter, the amount of urea is diminished or, at least, the proportion between the nitrogen of the urea, and to the total amount of nitrogen. Chief of all, the liver ceases to retain the carbohydrates, and sugar passes into the urine when the portal vein contains an excess of it after meals, and an alimentary glycosuria follows.

In order to test the function of the liver, the patient may be given, before breakfast, about half an ounce of syrup. If the liver is normal, no glucose will be found in the urine voided during the following four or five hours; if the glycogenic function is disturbed glucose will pass into the urine. Several conditions may interfere with the result. Although the liver may be insufficient, glycosuria may not appear, either because the intestinal absorption is hindered, or because the capacity of the cells for consuming sugar is increased, or, finally, because the renal emunctories are not performing their work normally.

If we study auto-genous poisons, we see that the living organism is always in danger of intoxication, even under normal conditions; poisons increase because new substances are produced by pathogenic agents; gastro-intestinal putrefaction is exaggerated and cellular disassimilation is more active, and often deviates from the normal type.

Many nutritive disturbances grow out of suboxidation. Our methods of civilization are responsible for this form of cell debility, which often leads to serious results. Among the very poor families food is deficient in both quantity and quality, and not in the proper proportion of albuminoids to carbohydrates. So we find in the children who are worked with insufficient sunlight, scrofula, enlarged glands, a poor quality of tissue, without resistance to inroads of the tubercle bacilli. Among the higher and more intelligent classes, we may have suboxidation from excesses of various kinds, excess in eating, irregular habits, loss of rest and sleep, and, among the more wealthy, insufficient exercise and over-eating. The balance between income and outgo is not maintained. The sugar in the muscles is suboxidized, and they have eczema or gout, which manifests itself as rheumatism in the muscles of the lumbar region, or, frequently, the heart muscle is crippled in its action. The suboxidized sugar enfeebles the circulation through the liver, and impairs its metabolic function in the final transformation of the crystallizable waste into urea, the normal diuretic, and when the antecedents of urea pass through the kidneys, chronic Bright's disease follows as a result.

Eating is only one factor in health; exercise and work, rest and sleep, the essentials. As to what and how much we shall eat must be left to that mental guiding power within each individual.

All kinds of vegetable alimentation represents a certain amount of vegetable life, which is transformed through the metabolic functions of the animal organism into animal life. But little is known as to the way in which one is transformed into the other, or as to the manner in which energy is set free and made use of as a life force.

To trace out the intermediate stages through which the constituents of the foods pass before reaching the final excretory products is accompanied with the greatest difficulty.

The manifestations of life are as varied as the different forms of individuals or plants or animals. All creation bears witness to its infinity and versatility, and inexhaustibility of resources.

625 Kansas Avenue.

[Written for the MEDICAL BRIEF.]

The Treatment of Exophthalmic Goitre.

BY ALFRED DE ROULET, B. S., M. D.,
Chicago, Ill.
Formerly Professor of Clinical Surgery and Diseases of Women in the Medical Department of Trinity University.

Generally speaking, the efficacy of the treatment of any disease is in an inverse ratio to the number of remedies or procedures advocated for its relief.

In the case of exophthalmic goitre, or Graves' disease, surgeons assure us that there is no real treatment aside from operation, but as to the particular operation indicated they differ widely. One school demands the extirpation of the greater part of the thyroid gland, another would cut off more or less completely the blood supply of the organ, while a third would remove the cervical sympathetics. Among physicians every effort is being made to develop a specific treatment. One feeds his patients on the milk of thyroidectomized goats, and reports wonderful results; another uses the serum of thyroidectomized sheep, and reports equally good results, while still others laud thyroid extract, thymus extract, etc. Among the older preparations belladonna, digitalis, opium, arsenic and the bromides are largely used.

As regards the operative treatment of exophthalmic goitre, we should bear in mind the fact that operations, no matter what their nature, often fail to cure this disease, and that the removal of the goitre often fails to relieve the symptoms. Again, an operation for exophthalmic goitre is much more dangerous than an operation for the removal of a simple parenchymatous goitre, the mortality rate being very high (fifteen per cent and upward), and sudden death during or shortly after operation painfully frequent. As a general rule an operation should not be attempted until medical treatment has utterly failed to give relief, or unless the symptoms have suddenly become urgent. Should operation be deemed advisable, a partial thyroidectomy, in my opinion, promises the best results. Clinically, it has been observed that in cases of Graves' disease where the goitre is very large its removal is accompanied by grave danger to the patient, and should the patient survive the operation the symptoms show but little amelioration. If the goitre is small the operation is seldom necessary. In hysterical patients, and the majority of these patients are hysterical, the operation rarely benefits the patient in the slightest degree.

The results of the non-operative treatment of exophthalmic goitre are considerably better than those attained by the surgeons. The principal objection to this form of treatment is the amount of time required, but if carried out with intelligence and perseverance good results will be attained. The course of treatment which I have found to be the most satisfactory consists of rest, diet, careful attention to hygienic surroundings, together with such medication as may be deemed advisable to control the various symptoms which may develop. Each individual case requires careful study, and the mental and physical peculiarities of the patient are often as important and should be studied as carefully as the more obvious pathological conditions.

In the treatment of mild cases of exophthalmic goitre little more than ordinary rational living is necessary. The patient should lead a quiet, regular life, avoiding excitement as much as possible, but doing a reasonable amount of work in a reasonable manner, practicing moderation in the pleasures of the table, going to bed early and getting up late. In severe cases a much more rigid regime is necessary before permanent improvement can be expected, and the patient should understand that good results can only be attained as the result of unremitting perseverance, and that the disease is one of sufficient gravity to make it worth his while to attend to the treatment.

Should the patient's circumstances permit, much benefit will be derived from a prolonged indulgence in the rest cure, but should such a course be impossible or impracticable, the following course of treatment will prove a very satisfactory substitute:

Given a patient with a well-marked case of Graves' disease, that is, with the

thyroid gland distinctly enlarged, a perceptible protrusion of the eye-balls, a pulse rate of one hundred and twenty or over, with nervousness, tremor, moist skin, etc. In such a case it is advisable to begin the treatment with from two to six weeks' rest in bed, followed by not less than twelve hours a day in bed for at least one year. Rest is much more likely to be taken if it does not demand too much of the patient's time during the day, consequently it is not a bad plan to instruct the patients to retire and rise at the same hour; that is, a patient going to bed at eight o'clock in the evening would get up next morning at eight. For the first few months, at least, eight hours a day should be spent in the open air regardless of the state of the weather, and as much as possible of this time should be spent in lounging in a hammock, etc. The old nursery jingle:

> "Never stand when you can sit,
> Never sit when you can lie."

is an excellent rule of conduct in exophthalmic goitre. There is practically no danger from exposure to the weather, as these patients are not susceptible to changes of temperature, and rarely take cold.

For the first week or two this aimless existence is likely to prove very tiresome to one of active habits, but in a remarkably short time even the most discontented will begin to realize and appreciate its advantages. Mental rest is as important as physical, consequently all occasions of excitement should be guarded against. Crowds, public meetings, theaters, clubs, etc., should be avoided. Occasional short visits from pleasant friends are usually beneficial, but visitors who wish to discuss their various troubles should be avoided. While reading in moderation is permissible, the character of the matter should be supervised, and all literature of an unduly exciting or emotional nature should be forbidden.

As the patient's condition improves a very moderate amount of exercise may be taken, preferably walking in the open air, but the exercise should never be carried to the point of fatigue. Physical culture exercises and systems should be given a wide berth.

The diet should be both full and varied, the object being to build up the patient's strength and to avoid any tendency toward flatulence or constipation. The food should be plainly cooked and consist of an abundance of meats, fats, as cream, butter and olive and cod-liver oil; cereals, such as well-cooked oat meal, cream of wheat or rice. The various patent breakfast nearfoods are of very little nutritive value. Fresh fruits and vegetables may be used freely. Tea, coffee and chocolate may be used in moderation. Sweets, pastry and made dishes should be used sparingly, if at all, while stimulants, as a rule, should be entirely withheld.

For the nervousness, which is an unpleasant symptom in many cases, codein gives the most satisfactory results. It may be given in doses of from one-quarter to one grain twice or three times a day, and may be continued for months without inconvenience or unpleasant effects. The best results are obtained when the drug is given for two or three weeks and then discontinued for a few days. Under its influence the nervousness is relieved, the pulse rate falls, the perspiration diminishes and the symptoms generally are much improved.

For the tachycardia digitalis and strophanthus have been highly recommended and in many cases are undoubtedly of great value. In emergencies cold may be applied directly to the thyroid or over the precordia with very satisfactory results in the way of controlling the tachycardia.

Electricity is sometimes of service in the treatment of exophthalmic goitre, though it is not much used at the present time. Two large flexible electrodes should be fitted to the front and back of the patient's neck, and connected with the secondary coil of a small battery, and enough current turned on to cause a slight tingling of the skin. This should be continued for not less than half an hour, and should be repeated twice or three times each week. The X-ray has also been used, and a number of cases have been reported where the goitre underwent a marked diminution after a

few exposures, the rays probably checking glandular activity and diminishing absorption by partially obliterating the lymphatics.

The use of the thyroid extract is based on the theory that all cases of exophthalmic goitre are not due to a hypersecretion of the thyroid gland, but that a certain proportion of cases are due to the elaboration of an abnormal secretion. According to this theory it is possible that supplying the normal secretion would prove beneficial, and in rare instances it does, apparently. As a rule, however, judging from the case reports at hand, it would seem that the administration of thyroid extract in such cases merely intensifies the existing symptoms. In the cases where good results are reported, the only advantages claimed are a slight diminution in the size of the goitre, and a more or less noticeable slowing of the pulse rate. The tremor and nervousness are not affected.

Renal Surgery—A Few Complications.

BY BENJ. MERRILL RICKETTS, M. D.,
Author of Surgery of the Heart and Lungs.
Cincinnati, Ohio.

Renal surgery has been so perfected and become so generally known that a discussion of the subject in its entirety would entail more time and space than is allotted to me. My object, therefore, is to present a few complications that have been encountered in approaching and operating upon the kidney viewed from a purely surgical standpoint.

These complications must of necessity bring the normal anatomy into question, as well as the anomalies likely to be encountered, not alone that of the soft and bony structures, but the position, size, shape and number of the kidneys and their ureters. It will not be necessary to consider the various incisions only as far as they concern the various cases in question.

Case 1. Nephrectomy.—White, male, aged twenty-seven; patient about five feet eleven inches tall, rather spare, with large, bony framework. Exploratory lumbar incision for renal calculi. The space between the twelfth rib and the crest of the ilium was long and narrow, so much so that the removal of the rib was seriously considered. It was with very great difficulty that the kidney was delivered from the incision, the pelvis opened and the ureters examined with a probe, with negative results kidney sutured and returned, with gauze drainage. Several months after, the patient, on his return from a summer resort noted for the efficacy of its medicinal waters in dissolving renal calculi, presented me with twenty-eight calculi of varying sizes, which he said had been passed. These, he assured me, he had obtained at two sittings within an interval of three weeks. A glance reveals their firmness, and indicates that they are not at all the variety found in the kidney or ureter. He has made a permanent recovery and is in absolute ignorance of my knowledge of his attempt to deceive me.

Case *2. Nephrectomy.*—White, female, aged sixteen, short of stature and rather fleshy; right lumbar incision, which revealed that space between twelfth rib and crest of ilium would only admit fingers, not being more than an inch in width. The twelfth rib was abnormally long and in removing it the pleural cavity was opened the entire length of the rib. The kidney was then delivered without further difficulty, and its pelvis opened for suspected abscess, which was not found. The ureter was sounded, with negative results, kidney sutured and returned to its position, and pleural cavity closed with catgut. Recovery prompt and uneventful. It is unusual for the pleura to extend to the twelfth rib. The fibers of the diaphragm normally touch those of the psoas and quadratus lumbrum muscles. The pleura more frequently extends to the eleventh rib, in the absence of the twelfth, and to the twelfth when the thirteenth is present, and seldom, if ever, extends to the thirteenth, which was not present in this case. In either event, the rib may be removed without opening the pleural cavity, if the soft structures and periosteum are incised along its outer surface, and the rib removed subperiosteally. This procedure should always be

resorted to when a rib is to be removed in approaching the kidney.

Case 3. Nephrectomy.—White, female, aged fifty-six, emaciated to a great degree, right lumbar incision for the purpose of removing enlarged tbc. kidney. An attempt was made to remove it retro-peritoneally by peeling the peritoneum down from the anterior belly wall. A rent in the peritoneum caused the peritoneal cavity to be opened and the kidney was then removed, through a combined incision. Recovery uneventful.

Case 4. Nephrectomy.—White, male, aged twenty-eight, condition fair; right lumbar incision for removal of enlarged tbc. kidney, the silk ligatures which were applied to the renal artery, vein and ureter, became detached immediately after removal of the kidney, necessitating the application of a right-angled forceps, which was allowed to remain in position four days, during which time the urine was free from pus. After removal of the forceps pyuria began and persisted for several weeks, the amount of pus gradually disappearing until, at the end of three months, the urine was normal.

This demonstrates that drainage of the perirenal space may occur through the ureter, which remains patulous after the operation.

Flat Foot.

BY ALBERT SILVERSTEIN, M. D.,

Professor Physiology Colorado College of Dental Surgery; Attending Orthopedic Surgeon to the Mercy Hospital.
Denver, Colo.

Of the many pathological conditions frequently seen by the general practitioner; and erroneously diagnosed, if not completely overlooked, none takes precedence over that condition commonly known as flat foot. Flat foot is of so common occurrence, its pathology is so well understood, though varied, the results of treatment so satisfactory, that this state of affairs is truly deplorable.

The patient complains of pain in the heel, the ankle, the inner border of the foot, great toe, the muscles of the calf, the knee, or even the hip. The busy practitioner, burdened, perhaps, by an overlarge office practice, sees the patient, notes these symptoms in a hurried, casual way, attributes them to rheumatism, prescribes salicylates and what not, and another flat-footed individual plods his weary way. Increased deformity is added to what may have been merely foot-strain in the first place. A curable case has become well-nigh incurable, and the medical profession is again justly liable to well-deserved censure.

And how can this be obviated? By the very simple procedure of exposing the foot of the patient. Prominent, bulging, internal malleoli and lowering of the arch, marked abduction of the great toe, or loss of the normal degree of dorsal flexion and plantar flexion of the foot are such obvious symptoms that a mistake in diagnosis can hardly occur. True it is that the symptomatology is not always in keeping with the manifest deformity. In other words, the foot may present a marked lowering of the arch, with inward rolling, and yet present few, if any symptoms. And the reverse is likewise true that a foot presenting few signs of deformity may have a well-marked symptomatology.

The special signs of diagnostic importance, from the standpoint of physical signs, is the marked eversion of the foot in walking. This everted gait is brought about by the inward rolling of the malleoli. Another marked physical sign is the loss of muscular power, as manifested in the diminished degree of dorsal and plantar flexion of the foot.

The etiology of this condition may be summed up in one statement: That any factor which tends to diminish the muscular power of the foot may cause flat foot. Such factors may be traumatic or postural. A great increase in the weight borne by the foot may cause this condition. This increase in weight may be actual, such as occurs in people who put on a great deal of fat, or it may be relative, such as occurs in athletes, jumpers especially. But by far the most common cause is postural. By this I mean more particularly a cramping of the foot, brought about by improper shoes.

The normal foot, as seen in an infant, or in an adult who has never worn a shoe, presents a triangular appearance of the sole, the apex of the triangle is formed by the heel, the base by the distal extremities of the toes. The base is slightly convex, the apex of the convexity being formed by the distal extremity of the second toe. The axis of the great toe, prolonged backward, passes through the heel. Now, one of the first effects of an improperly-made shoe is to cramp the normal foot. This cramping is manifested by an abduction of the great toe, so that the axis of the great toe prolonged backward strikes far to the inner side of the heel. Second, the muscles of the foot, from disuse, lose their power. The normal arch of the foot is maintained by the normal muscle power of the foot; this being lost, a relatively greater weight is superimposed upon the foot than can be borne, consequently the arch becomes lowered; with a lowering of the arch the muscles further lose their power; the peroneal group, the gastrocnemii, are affected, and thus a vicious circle is established.

For treatment of this condition, mechanical support to the deformed foot is practically all that is necessary. This mechanical support is best afforded by means of the foot plate made from highly-tempered steel and molded upon a plaster cast of the foot. The foot plate should be worn as long as it is required, but no longer. Additional wearing of the plate, beyond the time necessary as indicated by the symptoms, is simply an additional cause of harm. With the foot plate a shoe should be worn fitting the normal contour of the foot, a shoe which does not cramp the foot as a whole or any of its parts. Of great importance in treating this condition is a consideration of the muscles themselves. These should be massaged by passive motion, employed so as to restore lost tone. A cure having been established, the plate should be discarded, and properly-fitting shoes worn thereafter.

Among other conditions which might be mistaken for flat foot, is arthritis deformans. This need only be mentioned to be dispensed with. In arthritis deformans there is absolute limitation of motion at the ankle joint, caused by anchylosis. Arthritis deformans presents in other joints of the body. In flat foot, on the other hand, the loss of motion at the ankle joint is relative. Rheumatism, for which this condition is so often confused, can be readily differentiated by its very transient character and history of the case. The mere fact that the pain in flat foot may be referred to the knee or hip, should not mislead one, for an examination of the foot itself will nearly always disclose the true character of the condition .

Acne Vulgaris (Simplex).

BY P. T. KILGOUR, M. D.,

Professor of Practice and Dermatology in the Pulte Medical College; Dermatologist to the Protestant Home for the Friendless and Foundlings. Cincinnati, Ohio.

What more common or distressing skin disease among adolescents than acne vulgaris! The very nature of this disease and the time of its appearance make it difficult of treatment, notwithstanding the intense desire of the possessor to be rid of it.

Appearing at puberty, as a rule, when the human plant is in its juiciest stage, and activities heretofore dormant come into being, it is not to be wondered at that patients seek any and every means to be rid of its unsightliness, in many cases making use of unwise means to this end, and adding to, instead of relieving, the trouble.

In the majority of cases, the disease is due to greatly increased activity of the sebaceous glands, in common with the general glandular activity of the years intervening between puberty and complete physical development. It is but a step from physiological hyperemia of the sebaceous glands to congestion, especially if some influence is brought to bear to interfere with the function of the gland, either of a mechanical or reflex character. Comedones (black-heads), by plugging the outlet of the gland, bring about changes within the gland which result in the formation of first, a papule, and,

later, a pustule, and this repeated gives us the well-known picture of the pimply face. It may exist, also, without the comedone. The reflexes of gastro-intestinal disorders, flatulent dyspepsia, constipation, genito-urinary diseases, masturbation and, occasionally, affections of the nose and throat, all are to be reckoned with as causative factors. Idiosyncrasy is also to be borne in mind. The old truism that "What is one man's food is another man's poison," holds true here, with the skin bearing the brunt of the battle. The simplest kind of food may, in the so-disposed, cause congestion of the face, and thus keep up a continuous disturbance in its glands.

In no disease affecting the skin is it so important to get at the cause as in this one. Many times the correction of the diet will be all sufficient. In the plethoric the avoidance of animal foods and a substitution of vegetable diet will prove helpful. In the spare, scrawny and anemic an increase of nitrogenous food of the animal kind may be required.

Remembering that the skin is a very important organ of excretion, it is necessary to aid this function by the generous use of water internally and externally.

If water alone, externally, will not suffice to maintain cleanliness, the addition of soap, plain or medicated, and the use of such solvents as salicylic acid, boracic acid saturated solution hot, or equal parts of saturated solution of boric acid cold, and alcohol, are useful. In the sluggish and chronic type of this disease, occurring in thick-skinned persons, decided stimulation is called for, which is obtained by the use of Hebra's "Oriental lotion," or a milder formula is:

℞ Hydrar. Bichlorid .....8 grains.
Spr. Vini, Rect.....2 drachms.
Aquæ Dest.....4 ounces.

Ammonium sulpho ichthyolate soap and lotion are useful in many cases requiring mild stimulation, as also are resorcin (grains, ten to fifty to ounce) and beta-naphthol (grains, ten to thirty to ounce). The strength of ammonium sulpho-ichthyolate, as wisely suggested by Dearborn, should be graduated according to the degree of the disease, the texture of the skin, and, I might add, the toleration of the skin to this form of stimulation.

A popular treatment is the use of very hot water applied to the face until hyperemia is induced. It is best applied upon retiring at night, but should be preceded by the cleansing of the oily secretions from the face by means of good, pure soap and water, and followed by gentle massage of the face and the application of an antiseptic ointment of boracic acid, twenty to forty grains to the ounce of cold cream. These applications are valuable where the skin is sensitive. Like any other good thing, this practice of applying hot water may be overdone, and the very object of its use be defeated. If, after its use for a number of times, beneficial results are not obtained, it is well to suspend the treatment for two or three nights, and then resume. In very pronounced cases, where much pustulation is present, and the acne pustules show a tendency to coalesce and form sebaceous abscesses, the acne lance is indicated. This relieves the follicles of pus and congested blood, and will prevent the unsightly scarring that results from spontaneous rupture. Thorough cleansing with antiseptic soaps and carbolic acid, boracic acid, or salicylic acid lotions, should follow the use of the lance.

After-Care of the Parturient.

BY F. ABBOTT, M. D.,

Professor of Pathology and Hematology in the Denver Homeopathic Medical College.
Denver, Colo.

With the completion of the third stage of labor, our work as obstetricians is far from finished. At this time we have largely in our hands the future of two people. Gynecologists claim that if the two commonest consequences of parturition—injuries to the birth canal and retro-displacement of the uterus—were promptly recognized and properly treated one-third or more, numerically speaking, of the diseases of women would disappear from private practice. If this is true, there is the greatest room for improvement in this particular, and we can all draw conclusions from the number of

women we treat whose ill-health dates from confinement.

The after-care of the parturient, as practiced in the great lying-in hospital of Chrobak and Pischochek, is worthy of consideration. As the placenta is delivered the uterus is grasped firmly and all clots expelled. An attendant, who is trained in the work, massages the uterus for three hours. If the contractions are good, very slight massage with the tips of the fingers upon the fundus is sufficient to keep the uterus firmly contracted. If the uterus is inclined to be flabby, more vigorous massage is required. There is an art in massaging the uterus in a manner to keep the contractions good, and not be severe upon the patient. The fundus of the uterus can be easily reached by the tips of the fingers through the depression of the umbilicus, and pressure alone from that point is often all that is necessary to keep the uterus firm. If it relaxes, a gentle rotary movement will, usually, cause contractions. Obstinate cases may require more vigorous massage with both hands. The success of this treatment lies in keeping the hand constantly on the uterus. Just taking the hand away for an instant may allow the uterus to become so relaxed that it will be difficult to bring it down to the same small, hard mass again. I have carried out this method with primiparæ with most satisfactory results. When the contractions are as firm as they should be, there will be absolutely no clots, in the majority of cases, and less flow than is usual when massage is not practiced, although during the manipulation considerable blood will be expelled, particularly during the first hour. In a multipara, with a previous subinvoluted uterus, one can not expect as good results. In primiparæ I believe it is always possible to avoid displacements if the vaginal walls and the perineum are repaired, in case of lacerations, and the patient is not allowed to get up too soon, never before the tenth day, at least. In multiparæ the results are so favorable that one who has made a practice of massaging the uterus will always advocate it.

As to the use of the abdominal bandage there is a difference of opinion. When contractions are good, it is not necessary. Women who have worn them in previous confinements generally want them, and to some they give a sense of comfort. If there has been a tendency to hemorrhage the patient is safer with a bandage. When the patient gets upon her feet an abdominal supporter should be worn for a few weeks.

The bladder should never be permitted to become distended (if necessary, resorting to the use of a catheter), as it will crowd the uterus into an abnormal position.

During the first twelve hours the patient should lie upon her back, then she can lie on either side; if the uterus falls to one side she should lie on the other until it is again in the center. Later, if a tendency to retro-displacement is discovered, the patient should lie as much as possible face downward, until this is corrected.

The problem of greatest importance is the recognition and immediate repair of the perineum and vaginal walls. I believe that the skilled obstetrician can save many lacerations, especially of the perineum, and yet find there are lacerations in the vaginal walls, in spite of the greatest care, and these seemingly insignicant tears, if left, would not only be a foci for infection, but would cause a weakening of the vaginal walls, leading to prolapse, cystocele or rectocele. Very few physicians will leave a lacerated perineum without, at least, attempting an immediate repair, but many leave the vaginal lacerations to heal without repairing, when the perineum is intact. I have seen a case where a slight tear in the labia minora gave the greatest discomfort, where one stitch in time would have saved more than nine of annoyance.

If the laceration is not extensive, the repairing can usually be done without anesthesia, if done early. If there is delay, caused by slow delivery of the placenta, or other causes, an anesthetic is usually necessary. If the laceration includes the sphincter muscle, it should be faced as a surgical procedure. A physician should give the anesthetic. The work should be done on a table, with plenty of assistance, a good light and sufficient time taken for a thorough operation.

If conditions are such that an immediate repair is impossible, it is better to repair on the following day than to leave indefinitely. In two cases I have repaired in about twenty-four hours with perfect results. Last January a primipara, after a slow labor, was delivered without any visible laceration, the perineum was intact, and the vaginal walls, as far as could be seen, were intact. Later, the labia began to swell. The patient was of a very nervous temperament, and it would not do to mention laceration to her. The following day she was put under an anesthetic, presumably, to be examined. I found a jagged tear in the form of a semicircle, entirely above the pubic bones, going deep into the tissues; there were so many little radiations from it that it required eight stitches. She made an uneventful recovery. The vaginal walls are in perfect condition, and the patient told me recently that she never felt better in her life. Had the laceration been left to heal, I know she would have been a sufferer to-day. In repairing lacerations, if the parts are accurately coapted, and the stitches taken deep enough, the union will be perfect, usually by first intention. Of course, surgical asepsis must be strictly maintained. It is my practice to keep the stitches covered with dry dressing, usually boric acid, having it renewed every time the napkin is changed.

As to douches, there is also a difference of opinion. I never have any bad results from their use. I always see that the bag is sterilized, use boiled water in a glass douche tube. The douche adds to the patient's comfort, and, in reliable hands, never does any damage.

A source of infection which is easily overlooked, is blood spots. Unless the physician is watchful the nurse, if inexperienced, will often cover up a spot with a pad, instead of removing the soiled linen, especially if the supply is limited. If blood is allowed to decompose anywhere about the bed, there will be myriads of bacteria, which may easily infect the patient.

If there is one point more than another concerning which the doctor must be firm, it is upon absolute quiet for the patient. It is sometimes, seemingly, impossible to keep all the friends, relatives and neighbors out of the sick room, or, better, the house. Nervousness will often cause an elevation of temperature during the puerperium.

The chief purpose of this paper will be fulfilled if it emphasizes the importance of repairing all vaginal lacerations, however slight.

Temple Court.

[Written for the MEDICAL BRIEF.]

The Autocracy of Modern Medicine—A Circumspective View.

BY W. H. SMITH, A. B., M. D.,

Physician Local Board of Health; Surgeon C. R. I. & P. Ry., Etc.
Shell Rock, Ia.

In the request for an article at this time, there evidently existed in the minds of those soliciting same a desire to have the subject one with reference especially to the action of the State Board of Medical Examiners summoning me to appear before them to show reason why my certificate of practice should not be revoked for incompetency—*i. e.*, we differed in diagnosis.

As the facts are stated by the Court in so far as the case proceeded, it is, at this time, unnecessary for me to enter into the "equity" of same, but will, it having close connection with the subject, give it a few thoughts along the line of a circumspective view of modern medicine.

A very important decision, however, involving the right of a State Board of Medical Examiners to annul the certificate of a licensed physician and prevent him from practicing his profession was handed down by Judge A. H. McVey in the District Court of Iowa, for Polk County, "No. 13,826 Equity."

The Court granted a permanent injunction and delivered a very able opinion in which he says: "I am clearly of the opinion upon the whole case under the authorities that the right to practice medicine once being conferred and exercised for a number of years by a physician, is not only a right, but is the exercise of a liberty which amounts to property, and that the holder of such a certificate can not be deprived of his right to

practice medicine without due process of law."

"Under the statute had the board summarily proceeded and filed charges that the plaintiff was incompetent, his rights would have been forever foreclosed, because no appeal is provided by the statute, a condition of law which is repugnant to the genius of our institutions, and exposes the citizen to the charge of being deprived of liberty and property without due process of law." "In other words, where a statute reposes in a board or court the right to dispose of the rights, liberty or property of a citizen, fails to provide for a constitutional trial, the act is unconstitutional."

There is an element in human nature to which "imposition" appeals with a great deal of force. This characteristic is nowhere more noticeable than in the realm of medicine.

Some long-haired freak from the medical Hub, who, by a special dispensation of nature, is able to place himself before the public, immediately wins both an artistic and a financial success as one of the most remarkable phenomenons that ever emerged from the classic shades of the world.

Several years ago the conclusion was reached in this country that the time had come to protect the public, through legislation, from this growing evil, and a licensing board was established whose duty it was to inquire into the qualifications of practitioners of medicine.

Let us suppose for a moment that this object has been accomplished, and let us look at what the consequences of its accomplishments are producing.

The licensing board, combined with its auxiliary board the State Board of Health, whose personnel is made up of the same individuals, is becoming a powerful, and therefore a formidable body.

It can be powerful for good or for evil.

In which direction its influence will be cast will depend entirely upon the character of the few men who from time to time must inevitably control its destinies.

If they are honest, earnest and competent, its influence will make for good as regards both scientific medicine and medical policy, as well as including the rights and liberty of the individual.

If they, or a majority of them—or even a minority of them, if that minority should consist of men of dominating force—lack any of these three essential qualities, the board will become a menace to the public, and therefore to the profession.

Instead of safeguarding the people from incompetents and a few contagious diseases and bettering sanitary conditions, they now strive to supervise all sources from which life may be endangered.

"They make war tooth and nail on all sources through which tuberculosis and all similar diseases are disseminated with as much vigor as if they were small-pox or yellow fever."

"They give to the public antitoxin to combat diphtheria. They run a modern laboratory and make analyses for all physicians *free of charge*. They inspect localities where disease is reported to prevail. They disinfect all places where contagion is supposed to exist, and give free baths to all who apply."

This being the goal toward which they are striving, the fact becomes demonstrated beyond a doubt how entirely and arbitrarily despotic can be made the power assumed in the execution of their duties. There is a fear existing, and with good cause, that the object of this overelaborate body is not merely to aid the legislative purpose of better intellectual attainments and to assist in the procuring of improved conditions of public health and safety, but rather to govern everything connected with the health situation of the universe. It is not governing which the public stands in need of today, but co-operation toward honest intellectual development.

"At present we are in danger of too much interference of the licensing body with the teaching body."

If we were to ponder over the words of some of the greatest medical philosophers that have ever ornamented our medical profession, we would view in their jealous, anxious and thoughtful eye the threatened honor of our teaching body—the medical school—separate, but governed by these Procrustean methods that now seem to be in the ascendancy, opening the way to some of the most unrea-

sonable, unscientific possibilities that can be imposed upon the individual and public.

Through a process of continued delegation of authority the power must ultimately resolve itself into a dictatorship or an oligarchy in effect, if not in name, and arbitrary insults may be continued so long as the people do not give an intelligent and efficient attention—through legislators—to the laws of disease, not only the modes by which the disease is propagated, but to the duration of the dangerous activity. In other words, all real progress towards the control of disease dangerous to the public health must come through the enlightenment of the people, safeguarded by a system of differential diagnosis.

When you hear some loud-mouthed, saintly individual shouting: Danger, danger! beware of danger! keep a sharp eye on him; he generally has some selfish and spiteful motive.

"Just think of some of these intellectual hypocrites who devote their little brains to some unreasonable sophistical chimera they themselves do not know any more about, than a chimpanzee knows about the principles of this government."

There is a tone of optimism in this which seems to have foundation in the various quarantine conflicts of the past few years.

When the State is repeatedly aroused, and its citizens kept awake by the disgraceful howlings over the outbreak of some contagious disease, characterized either through ignorance or a desire to distort facts and ignore all the vital questions of honesty and integrity, it should not be expected that the public will accept the outcry without question of its genuineness.

When, as in the year 1904, an eruptive disease appeared in this county, and several physicians saw and diagnosed the disease as chicken-pox, a member of the State Board of Health, notified of the existence of the dispase, came into the locality, diagnosed the disease small-pox, rode rough-shod over the local board with assumed power to remove them from office, deposed the local health officer, took full charge of the situation, appointed another health officer and instituted a system called quarantine.

The local authorities sought legal and medical advice. Several affidavits and opinions were procured from competent medical men. Among these, one in his own characteristic handwriting given from description of facts, we herein quote. This opinion was given but a few days before his death, and almost the last day in which he was at his office:

THE DESCRIPTION.

"We are having in this locality quite a sensation over an eruptive disease, and, as usual, a difference of opinion, and for our satisfaction will give you a brief description requesting your opinion in diagnosis.

"The disease has existed for some months over quite a territory; is contagious; exceedingly mild; in reality, no one needing medical attention; attacking adults in many cases who seem to have the disease more severe than among children.

"In the commencement is a slight indisposition, headache, pains in the back and body; little fever, etc. Within twenty-four or thirty-six hours the appearance of a rash; distinct, macular; not accompanied with hard base; no areola; each twenty-four hours for three or four days a succession of the eruption, which from the first passes through an irregular course into blebs, conical in shape, filled with a serum, clear in many; others of yellowish color, which, in same course, gradually settle down into dry, dark scabs or scales, involves epidermis, and usually leaving no scar or mark, and working alike in both vaccinated and unvaccinated persons, etc.

"Disease is diagnosed as small-pox by a member of State Board of Health.

"If, from above description, you can give an opinion, please do so upon paper hereto attached. [Signed.]

THE OPINION.

"CHICAGO, ILL., May 31, 1904.
"65 Randolph street.

"From the description given in your accompanying letter I should regard the disease described as simply *varicella*, chicken-pox.

"Your description does not include any *diagnostic* symptoms of *small-pox*, or any of its modifications.

"From the uniform mildness of the disease, it seems to require only simple hygienic treatment.

"Yours truly,

"N. S. DAVIS."

(Underlines are his.)

Suffice it to say that after recovery I vaccinated about thirty patients with the results usually procured in unprotected persons.

General Grant used to tell this story to point a moral. It seems it might point the same moral today:

"The General told how his whole camp was kept awake nights by the outrageous howling of coyotes, and they were satisfied that millions of the natural-born agitators were just over the hill. A band of venturesome soldiers rode out to get a shot, and found just three coyotes, each on his own knoll, contributing all the noise."

There is no kind of disease so hard to diagnose as certain classes of skin diseases. It is almost impossible to determine from the eruption what the exact trouble is. It is necessary to inquire into all the facts pertaining to each individual disease. Is the disease epidemic? Is there a history of exposure? When was the patient taken sick? What were the preliminary manifestations? are all questions that should be asked and carefully weighed before the eruption itself is taken into consideration.

These questions satisfactorily answered, the careful physician will not then be in too great haste in giving a positive diagnosis.

It is just this safeguard that the people stand in need of today.

The professor of diseases of children in one of our leading medical schools in a recent lecture to young physicians had this to say: "The public should be taught that scarlet fever is a highly contagious disease; that it is dangerous to life, and that it is a very frequent cause of deafness and other organic and functional defects.

"Do not be too hasty in forming a diagnosis, but wait until a sufficient number of distinctive symptoms have shown themselves before you pass an opinion as to the nature of the disease.

"Every case, mild or severe, should be isolated. In other words, if called in early do not be afraid to tell the friends that sufficient time has not elapsed to give a positive diagnosis, and that you may have to repeat your visits several times before you can do so. When you are certain your diagnosis is correct, and you have a case of scarlet fever, strict quarantine should be established.

"When a physician or a number of physicians see fit to diagnose a disease, and when this opinion is reached without giving due, accurate and intelligent consideration to the nature of all conditions and results, it is imposing, unfair, and is deserving of censure on the part of all citizens; and worse when they, from neglect or otherwise, fail to heed these teachings and defend their mistakes with the idea 'that it is many fold better to make a mistake in ordering quarantine established in disease' the character of which is not exactly known than to neglect to quarantine a case where contagious disease exists, is a travesty on justice, a mockery upon liberty, and a reflection upon the intelligence of our American institutions."

In an honest attempt to carefully analyze the legitimate rights of all parties interested, if intelligently and properly executed, it might almost seem possible to relieve the American people from often having to tamely submit to some brazen imposition which manifests the apotheosis of impudence in the name of the State.

This may hit some of our social and professional blunderers pretty hard, but to every person who has an eye-piece to see and a head-piece to think, it must be apparent that we can not do otherwise and tell the truth.

The longer one studies the scholastic and political sides of medical education the more forcibly he becomes convinced of the necessity of formulating a scheme of study, purely ideal, and then work to adjust it to the requirements of the body politic without attention to facts and circumstances, or the probable consequence of a measure with a view to a correct course of conduct.

There is, however, every reason to feel gratified at the substantial progress that

has been made in our medical schools, and upon this progress, coupled with a careful compilation of facts, it supplies a basis upon which can be erected a rational and substantial tombstone.

The *International Journal of Surgery*—editorial article—notices chances for improvement in our teaching body. It says: "Primarily, the function of the medical school is to fit men to practice medicine—for this too much attention has been paid to laboratory work—even to the extent of encouraging experimental research on the part of the undergradute."

"Medical colleges would do well to reinforce their course by devoting more time to emergency medicine and surgery, and professional economics and customs."

We should no longer hold medicine a mystery, but we should take mankind into our confidence and strive to educate the masses along the lines of truth as we know it.

I am aware that disappointment will be your lot if something is not said relative to the long list of diseases extending from Alpha to Omega in which I was charged with incompetency. Yet nothing we can say in truth or in malice can dim the splendors or make sensible, useful and beneficial the value of these devotees to some humane institution like a home for honest politicians or a college for domestic servants.

The summons was legal, and therefore compulsory. We made it as funny as possible, but essentially it had to be. If our ideas of fun should see alteration, the inquiry unfolds natural results in giving the masses enlightenment of a life condescendingly deprived of equal rights and justice.

The ideal arrangement for this subject—as per *Collier's*—would be one paragraph of words, one of emotion, one of history and one of poetry, to which we plead incompetency, not being able to furnish all the ingredients, although something does fuse into action a quotation:

"A bellicose bug met a taciturn worm on a twig most alarmingly narrow.
Screamed the bug: 'Let me pass; you impertinent germ!'
And began to show fight, but the other stood firm
And silently faced him, with never a squirm.
On a twig just below sat a sparrow.
Thus they stood; eye to eye, this belligerent pair;
But the worm's gaze would chill any marrow.
A few passes he made, then, with mesmeric stare,
With a hyper-compulsory, hypnotic glare.
He made that poor bug, minus bellicose air.
Drop down to the welcoming sparrow."

It is immaterial whether these acts were due to single-minded devotion to the public good, or were simply the crafty use of a worthy object for purely selfish purposes.

I have the consciousness of feeling, as I look into the motives of the case, that the only selfishness that I have is the desire to do right, to be a benefactor of my race, and I sincerely hope that my labors may be blessed so far as they tend to relieve suffering humanity, to advance the cause of science and to elevate the "principles" of medicine.

"It is a glorious thing to feel that you are above the dross and glitter of pageantry.

"Money is trash, and may be blown away by the wind.

"Honors are evanescent and may be snatched by another.

"Even reputation may be tarnished by the slanderous tongue of an envious villain, but the proud consciousness of rectitude, coupled with benevolence, lives in the heart of its possessor, and is as immortal as life itself."

Practical Notes.

BY DR. A. ROSE,
New York City.

One of the most valuable practical suggestions of recent years is that of Dr. Stephen Harnsberger, of Catlett, Virginia.

Potassium Bicarbonate in Colds and Influenza.—Given early it will, in nearly every instance, abort a cold very effectually and promptly. Well borne by both elderly and weak persons; in fact, adaptable to all ages. The dose for an adult is thirty grains in a cup of hot milk every four hours during the day, and no other diet for forty-eight hours but hot milk. When milk is not well borne, or

readily taken, administer the remedy with a glass of water, and allow only liquid diet. The action of potassium bicarbonate is assisted by a cathartic, and none is more suitable than compound licorice powder. *It is the most effective of all remedies in case of influenza.*

When to give Quinine and when Methylene Blue in Malaria.—Methylene blue will have a curative effect in those forms of malaria in which the plasma is most developed, and quinine in those in which the nuclei are the most developed and the plasma more or less wanting. The form which is most decidedly affected by methylene blue is that of the crescents, which consist almost entirely of plasma, while on the other hand juvenile forms of plasmodia which have very little plasma remain unaffected by methylene blue, but are very sensitive to quinine. The full-grown parasites, the principal part of which consists almost entirely of plasma, are indifferent to quinine but most sensitive to methylene blue; they are completely destroyed by it. There exists, as we see, an antagonism between the action of methylene blue and quinine; the latter destroys the nucleus, the former the plasma. In acute malaria quinine will be indicated, in chronic malaria methylene blue. The dose of the latter is a one-grain pill every two hours, *i. e.*, six pills daily, to be continued for one week. The effect of methylene blue in chronic malaria is as striking as that of quinine in acute malaria.

To Relieve Itching in Urticaria.—Perhaps the most reliable remedy against this and some other forms of itching is salicylic acid, one drachm dissolved in six ounces of alcohol. Apply to the itching skin by means of cotton. There is at first a little, but hardly unpleasant smarting, followed by relief.

Vomiting.—Two drops of tincture of iodine in a tablespoonful of ice water, every two hours, will control vomiting in most cases. For vomiting in pregnancy: Chloroform and tincture of iodine equal parts; of this mixture five drops in cold water every two hours.

Chronic Gastritis.—Bismuthi subnitrici, magnesia calcinatæ, equal parts; well mixed. Of this mixture a teaspoonful in water half an hour before each meal. Magnesia will dissolve the slime, the characteristic feature of chronic gastritis; bismuth acts as a mild antiseptic. As a rule, within a week there is marked improvement. The first benefit generally noted is the disappearance of gas in the stomach, the correction of raising phlegm, especially in the morning, the regularity of defecation and general change from depression to sereneness. No matter how well the patient feels, the powder should be continued for about six weeks. Patient should be advised to eat slowly; to masticate the food well.

Medical Wonders and Medical Blunders—A Story of Facts.

BY M. J. RODERMUND, M. D.,
Milwaukee, Wis.

CHAPTER XXV.

SCIENCE AND ART.

Science is classified knowledge. The word itself in its etymology signifies what we *know* about a particular subject. Whenever we learn two facts about any subject and we differentiate and classify those two facts, we have a science of that subject. Thus we have the science of astronomy containing the classified facts that intelligent observers have learned concerning the stars, the science of mathematics, a classification of knowledge concerning numbers; and we have the science of medicine, consisting of facts that intelligent observers have collected concerning the physiology of man, the etiology and pathology of disease classified and reduced to rules to serve a practical purpose. I make these few remarks in order to draw a distinction between a science and an art.

The science is the classified knowledge; the art is the process of turning that knowledge to practical account. The two words, "Science" and "Art" are usually used synonymously in medicine, and their broad distinction should be established to avoid confusion. The science of astronomy never discovered a star; the science of arithmetic never computed the value of a fraction. The sciences are merely cold, hard facts, piled up in crys-

tallized principles and rules. *Art* is the warm, living application of these principles and rules to serve the needs of mankind.

So with the science and the art of medicine. The science is as absolute as mathematics. In its principles there are no fallacies. To its rules there are absolutely no exceptions. The *Art* of medicine, on the other hand, is estimative, and the results of its application will depend on the graces, gifts and abilities of him who seeks to apply it. To illustrate, the process of digesting the foods and their appropriation to the wants of the body is an absolute science. In its principles there are no failures or exceptions. But the application of these foods is an *Art*, and is only estimative, and it depends often, if not largely, upon the knowledge of the individual to properly apply the proper kind and quantity of foods best adapted to him or herself, according to their constitution, environment and vocation. This article closes the first year of the series of my articles published in the BRIEF. In these articles I have confined myself to the science, postulates, blunders and crimes of the profession. If I should continue the series, which at present looks very doubtful, I will confine myself to the Art of Medicine; in other words, the practical application in the care and treatment of disease, as well as to their efficacy in the maintaining of health and a long life.

Physiology and pathology, as well as the action and effects of our environments or atmospheric conditions upon our physiology, and in the production of pathology (disease), is an absolute science. The adapting of ourselves to these two great sciences for the maintaining of health and long life, or the prevention and cure of disease, is estimative. In other words, it is an *Art*. As before stated, physiology is an exact science, yet it differs mathematically in each individual, this is especially true among civilized nations; hence the necessity of each person to have more knowledge upon the subject in order to receive its full benefits. In some directions physiology has made great strides, yet is of very little practical value compared to what it should be if it were not for the fact that the "key" to this magnificent science has been completely ignored by the medical profession. I refer to mental physiology, or, rather, phrenology. Phrenology, practically applied, is an art, and is estimative, and in its delineations includes the whole physiology of man. The meaning of the word phrenology is at present misconstrued as to its full meaning, similar as the word artery means air-pipe, but in reality is a blood vessel. The word phrenology in an early day, by the laity was used as bumpology of the brain. The fact is that the art of phrenology is the applied "art" of the "science" of the brain, and is the most essential key to the perfect understanding of physiology. But you may ask me, "Is phrenology sufficiently developed to be of practical value to mankind?" I answer unhesitatingly that phrenology is the reigning queen of all sciences, and is of greater value to the human race than all other sciences combined, because humanity is worth more than all the stars that scintillate in the heavens. It is greater than mathematics, because humanity is better than numbers; greater than geology and zoology as humanity is above the rocks and animals, and greater than all combined because phrenology bears upon her resplendent crown the jewels of knowledge, virtue, morality, culture, temperance, wealth and progress, and is pregnant with possibilities of good beyond the present comprehension of the human imagination. Let me make my meaning clear. The function of the stomach and intestines is called "digestion," yet digestion, to be perfect, depends much upon the perfect or balanced relation of the digestive organs to other organs and functions of the body. This same illustration holds good with the brain. What we have called mind or intelligence, is simply the functions of the brain. The brain is adapted to perform these functions, just as the stomach and intestines are adapted to perform the functions of digestion. Just as good digestion depends upon the correlative relation to other functions does the correlative relation of the brain and its capabilities of performing its functions depend very much upon all other functions of the brain (intelligence), and on the other hand, whatever affects intelligence affects the body. The

body is like a harp of a thousand strings, manifesting its intelligence by different degrees of vibration. If either the musician or his instrument is out of order the music will be discordant. The neglect of medical men and many laymen to comprehend the full meaning and the inseparable relation of these laws is undoubtedly the reason that they have not comprehended the fact that phrenology is one of the most important branches of physiology, and without it have ignored the most glorious and important branch of the medical curriculum. Without this knowledge the physician is handicapped to explain the cause of many ailments. Without this knowledge the layman is unable to govern his acts correctly in order not to lay the foundation for a chronic and incurable disease. For instance, thousands of people, especially in this country, are suffering with indigestion or dyspepsia, and are being treated for such, but without the slightest benefit, because of the fact that nothing is really the matter with the stomach pathologically; but their unbalanced physiology is such that the brain capacity overshadows the digestive and circulatory, and attracts the blood to the active brain that the stomach needs to perform its normal function (digestion). It is apparent that medicine will do these patients no good, but that the proper advice to the patient as to its cause, and then to have the patient correct this error, is the only remedy. Such a patient, as a rule, is by phrenologists called a mental temperament, and proportionately deficient in the vital temperament. A practical knowledge of phrenology will tell the physician at a glance that this patient will complain of some trouble of the digestive organs, and without this knowedge will likely dope him with medicines for months and years until some incurable condition has developed, while the knowledge of phrenology would have prevented this error and given the patient a lease of life of ten to thirty years longer. The proper advice would only give the doctor one fee, where the present method gives him regular fees for months and years, besides being of no benefit, and ultimately costing the patient his life. This reminds me of a man who, for several years, was treated for dyspepsia, when, in reality, it was the over-working of a brain with a deficient vital temperament. He gradually grew worse, took to his bed, and his wife called in the family physician and another specialist in consultation. Both physicians decided that they could not do anything for him, and that he had but a few hours to live, and so informed the wife and the patient. The man then asked the attending physician how much his bill was, as he wished to settle all his accounts before he died. The doctor said: "Six hundred and fifty dollars." The consulting physician replied to the same question: "One hundred and fifty dollars." The physicians were paid in full. The patient then said to one of the physicians: "Doctor, take hold of my hand," and to the other, "Take hold of my other hand." All remained silent for a time. when one of the physicians inquired why he wanted them to keep hold of his hands. "Well, I will tell you," said the patient; "seeing I must die, I want to die like Christ, my master, between two thieves."

Granting, then, that the American people have the great desire of maintaining health, if they only knew it it goes without saying that all real knowledge of nature pertaining to the subjects of health and disease must be proportionately detrimental to the financial end of the medical profession. But doctors and disease are on the increase every year. There must be something wrong somewhere. Where is the wrong? It is simply this: The medical profession are continually springing false theories and practicing deceptions and frauds of the grossest nature upon the public which misleads the public and keeps them going and acting in the wrong direction instead of the right.

Just stop and think what it would do for the public health, the millions of lives it would save and the millions of dollars it would save the public if the simple principles explained in the former chapters were continually kept before the public. Teach these simple natural principles thoroughly in the public schools. Educate the young that marriages must be based upon the principles of phrenology and physiology; that this is the *only*

method of stamping out consumption (barring the sporadic cases). Teach the public that each one is responsible for his own diseases, and that no one can contract a disease by contagion; that quarantine is useless and dangerous, and that germs are the cause of diseases is all tommyrot. Teach the public that our prominent surgeons are the greatest criminals on earth. Teach them that the cases that need an operation could be mostly avoided if properly attended to in the beginning. Teach the public that the atmospheric actions and the acts of the individual, singly or combined, produce all diseases man is heir to. Explain in detail how these two causes produce the various forms of disease. Teach them how simple most all diseases can be treated by themselves by very simple methods in the beginning of feeling ill. Teach them the cause of epidemics and that the eruptive diseases are the least dangerous, the easiest to be prevented and the simplest to be treated of all other diseases. Teach them that small-pox and scarlet fever are the accumulations of the identical poisons that the body is eliminating every moment of our lives. The public should be convinced of the fact that the medical profession consists of the greatest ignorance, pretenders and frauds according to nature's methods of doing things, and that very few deserve the respect and confidence of the American people.

Now, I do not want to be misunderstood, and that I am only writing for the sake of finding fault; far from it, as I prefer to throw bouquets, as I am a physician myself. My early experience soon taught me that most of those wonderful theories and the good we could accomplish taught us at medical college was a farce, and injurious when practically applied at the bedside. To say the least, I was a much disappointed man. I made a vow that I would devote all my spare time to investigation, observation and experiments, and, if possible, find the cause of disease. I believed that disease was contagious as well as many other fallacies. I would be called to a family and would find several cases of diphtheria or scarlet fever. It struck me, How is it possible for me to prevent carrying these diseases to other families, and especially to my own family. I could conceive of no method that if disease was contagious how it could possibly be prevented. Yet I found that I could not carry a disease to another, and that epidemics came and went in spite of any of the damphool regulations. I was determined to know something about this subject. The previous chapters have explained the result of the twenty years of work along these lines. The attitude of the profession has only been a repetition of the black and disgraceful history of their past. In the past they have fought tooth and nail each and every time any fact or truth that would overthrow established false and injurious theories which they had in various ways put before the public, and have the public accept them as facts. Not only that the medical profession have, in each instance, directly or indirectly ruined every man who presented absolute proof by the laws of nature that overthrow their established fallacies and atrocities. This was true of Dr. Harvey, who discovered the circulation of the blood. It was true in the overthrowing of bleeding and blistering. It was true of Dr. Thompson, and many others. But let any man come out with a theory or method that will be a success from a mercenary standpoint, and he will be lauded and praised, and his name made famous and immortal. The public have repeatedly asked me, Why, Doctor, don't you publish those principles of yours in the medical journals, and let the profession investigate and discuss them; that surely physicians are not all dishonest? What has the past year demonstrated? In closing, I take this opportunity to thank the Editor of the BRIEF for the broad, liberal and tolerant spirit in publishing the first half of the series of my articles; the other half will likely not be written at present. I have no other object in view but to improve and benefit the medical profession, to expose the rascals and to give to the public what they have for centuries been craving for, but have never received; that is, the cause, prevention and treatment of disease.

Is Beauty Its Own Excuse for Being?

BY AXEL EMIL GIBSON, M. D.,
Los Angeles, Cal.

"The guaranty for true religious honesty lies in our worship of beauty—beauty as an abstract principle—independent of all the circumstances resulting from it. On the other hand we have utility, which is always modified by, and dependent on events."
—MME. STAEL VON HOLSTEIN.

One of the questions which for ages have agitated the minds of men relatively to life and progress is found in the meaning and character accredited to the manifestation of beauty. Has beauty value and significance in and through itself, or does it serve as means for the accomplishment of utilitarian ends?

And as beauty, whenever made manifest in objects and processes of the concrete world, through the genius and ingenuity of man, gives rise to art, it follows that the same question facing beauty and its relations to utility, with equal force and logic confronts art in its relation to motives of morality and civic virtue. Thus, we raise the question: Is art for art's sake or for the general progress sake?

In this, as in all questions of life and growth, the final appeal must be directed to the infinite, ever-present, ever-active energy which at once impels and directs the movements of universal evolution. It is to this mystic face behind the veil of the concrete and changeable, from which life and consciousness, as causative factors, unfold their spontaneous impulses in terms of progressive nature, that the serious inquirer must look for a solution to his problem. This face of the world-sphinx looks at us from every aspect of natural evolution.

The first glance at nature reveals the fact that throughout all her kingdoms the lines of the beautiful and the lines of the useful unfold in diametrically opposite directions. The formula—unvarying and fundamental—expressed in all animate and inanimate nature reads: The more imperative a factor is in natural or social evolution, the less marked is the beauty of its features or the processes of unfoldment.

Thus, at the very base of the evolutionary ladder—the mineral kingdom—we are met by the striking contrasts between the zone of the beautiful and the zone of the useful. For what is more useful in the mineral world than the granite and the iron, and at the same time less beautiful? And thence, upward or downward—according to our consideration of the beautiful or the useful—along the entire gamut of the mineral world, wherein the dazzling exhibit of the gold, the diamond and so-called precious stones, we meet so much beauty and charm with comparatively so little usefulness to man.

And this principle operates with equal force in the very soil we walk on, which, with its priceless value for the material progress of humanity is most unattractive, and never elicits a single thought or feeling of the sublime and beautiful in existence. Thus, in the humble granite, the clay and the sand, etc., despite their ugliness of form, emptiness of expression and cheapness of price, we meet qualities of usefulness so fundamental that the commonwealth for its commercial and structural integrity absolutely depends on their employment.

In the vegetable kingdom, the same inverse relation obtains between the useful and the beautiful. Its signature remains invariably the same; the more beauty the less usefulness. The ugliness of the potato, the carrot, the beet, turnip, cabbage, the grains and grasses—the prime factors for the support of the organized world—is as striking as the beauty of the lily, the rose, the chrysanthemum, the pansy, etc., coupled with the utter invaluableness of the latter in the vital economy of nature. The apex of beauty coincides, with very few exceptions, with the apex of the concretely useless.

The parallelism thus traced in the mineral and vegetable continues with unabated force in the animal kingdom. In proportion to their domestic usefulness, the animals exhibit angularity of form, gracelessness in movement and correspondingly physiological and anatomical imperfections. The domesticated beasts of burden—the plug horse, pack-mule and ass, the milk cow and the hog—so indis-

possible for the material progress of the commonwealth—do certainly not appeal to our sense of the beautiful, while the wild animals, unburdened by any service to culture, exhibit features and qualities of highest grace and beauty. We need only refer to the zebra, the antelope, the tiger, the lion and eagle, etc., and the striking contrast between their fascinating but relatively useless beauty and charm, and the useful but homely and awkward hen, turkey, goose, duck, etc.

These lines of contrast between the beautiful and the useful can be pursued into the region of the highest kingdom, to the human mind itself, in the work which genius and intelligence have wrought in art and culture. For, is not a poem by far a greater work of beauty than a scientific lecture or a technical invention? Or do we ever find in the elaborate and laborious statements of general philosophy the pathos of life and the vision of beauty which exalt us in some great classic work of fiction? And even in art's own realm of being, is not the fairest, the sweetest, the most divine and most beautiful of them all—the art of music—also the one who, in natural evolution and in the concrete progress of the world, shows the least appreciable sign of usefulness.

Nor is man himself, as a type in evolution, exempt from this universal rule. The men and women who serve as vital props in the social structure of the commonwealth—the manual workers, producers and wage earners—do not, can not, express the refinement of touch, dignity of movement and beauty of form which we meet with in the privileged laborers in the vineyard of the beautiful—the representatives of genius and inspiration—the artist, the poet and the seer. For what are the groupings of human anatomy, especially in the delicately-poised ligaments of the face, but the action of thought mirrored in the features and facial expression of the thinker—an expression which, with no exception, rises in sublimity and beauty with the spiritual ascendancy of the subject under contemplation. Who can fail to observe the difference between the keen-edged, aggressive, often even gross expression of the scientist, especially if his researches are gauged by dominating materialistic motives—and the lofty, sublime touch, the gentleness of demeanor, and unassuming yet dignified poise of the poet and artist. From the man with the hoe—the alleged representative of the useful, the concrete and indispensable phase of the prosperous commonwealth—up to the man with the ecstatic vision, the man with his mind suspended in the empyrean, the practically inappreciable man, whose entire struggle, dream and hope, motive and destiny are enveloped in the life of beauty—we observe a constant elevation of the individual type toward the abstractly beautiful and soul-inspiring. Evidently, the spiritual ascent of life is rising *pari-passu* with the ascent of the beautiful, in inverse relation to the useful.

And even among the men of genius themselves, in definite proportion to their divorcement from utilitarian pursuits, we find this rule in operation. Thus the genius of constructive intelligence whose mental center of gravity lies in the useful and materially progressive, does not possess in his character and expression that overwhelming cohesive force of the ideal, the resistless power of the divine to stir the soul into emotions of at once courage and sweetness, of mountain-firm resolve and forbearing tenderness; the power to lift the whole nature of the responsive beholder into regions of soaring, sense-withering beauty. For even genius has its sliding scale of beauty, on which it descends or ascends in proportion to the dominant tendency of the mind towards the constructive or inspiring; the concrete or abstract; the intellectual or intuitive; the aims of the useful or the aims of the beautiful.

It would be utterly unreasonable to suppose that such a chain of unbroken evidences could stand for the workings of mere chance and fortuity. There must be some leading, explicative basis for these ever-present inverse relations between the categories of the useful and the beautiful, as they unfold in unbroken series all along the lines of physical, mental, moral and spiritual evolution—a basis which probably can only be found by admitting into the human equation

the factor of soul. For as the body of man requires for its growth and evolution the concrete substance of material elements—the shocks of sensory nerve impulses—so the soul for its unfoldment requires the ecstatic impulse of the beautiful. The soul feeds on the beautiful, absorbs and assimilates its powers into its spiritual constitution. And as the body forms a vehicle or agency through which the physiological processes of the material universe finds a means and method for its elemental evolution, so the soul represents a living force-unit by which the spiritual universe through the idealizing power of beauty wields a means and method of self-realization. The soul cultivates the ideally beautiful, as the body cultivates the concretely useful; and as the latter fashions its stuff into living anatomical structures, so the former, in absorbing its undefinable pabulum of divine beauty, generates ideas and concepts of the true, the good and the sublime.

Yet, to be an evolutionary force, the impulse of beauty must be met with concrete and conscious response. To the closed and isolated mind, beauty will remain a closed and inaccessible sanctuary. For the only mode of responsiveness to which beauty shall ever yield is love. Love is to the soul, in relation to the beautiful, what hunger is to the body in relation to food; which again means that the admiration and contemplation of the beautiful stands for that process of physiological absorption by which a vital system is enabled to assimilate and organize its nourishment into available qualities and powers. Hence, to ignore the beautiful, *i. e.*, to fail to observe its manifestations with love and admiration, means to the soul and its growth what the disregard for physical nourishment means to the body, the gradual decay and dissolution of the dependent entity. Without a power to love the beautiful, the individual shall remain a groveling brute, dead to everything but the thrall of a mere sensual vegetative existence.

For beauty is the lodestar of life, the mythical Ariadne-thread, guiding the soul to its destiny through the bewildering labyrinth of gross, sensuous, passion-wrought existence. Forever upward and onward, like Aurora on the wings of dawn, blazing out the course for the advancing solar-majesty, the divinity of beauty illumes the career of the human soul as the latter proceeds on its pilgrimage through universal evolution. To lose the guiding influence of its powers, means to be left to stalk about aimless and helpless in the ever-shifting vicissitudes of material existence, conscious of nothing but the mean, circumscribed wants of mere intellectualized brute life.

Any attempt to utilize beauty by enlisting its service for the furtherance of material progress degrades it. For beauty is not an evolutionary steam engine, by the action of which the profits of cultural and industrial operations are enhanced. It is an ecstatically vitalizing, inspiring force, not a mere dynamic agent. Its mission is to guide and direct rather than to move and propel. To employ its powers as a dynamic lever for the furtherance of general progress involves the same principle as to use the searchlight of an ocean steamer for the generating of steam in its boiler. Would the temporarily increased speed of the vessel compensate for the loss of the guiding flashes by which the ultimate progress and safety of the navigation is to be made possible? The light of beauty, like the mythical fire of Olympus which Prometheus brought down to serve the small aims of earthbound men, can suffer the degrading touch of utilitarian motives only at the loss of its inspiring and guiding genius, leaving the transgressor on his fatuous Caucasus to work out his destiny in guideless and powerless isolation.

For beauty is not a mere sentiment—a fragrance, as it were—ephemeral and meaningless. Beauty is a cosmic force, wielding in its sweep the whole scope of spiritual evolution. In itself non-moral, beauty becomes moral or immoral, according to the standard of motive applied by the poet or artist in his effort to interpret or translate its genius. And as beauty is thus colored by its imported motive, and furthermore as any coloring, however apparently pure and elevating, must, by its very nature be personal, hence limited and more or less untrue, it follows that art, to be pure and spiritually legitimate, must forget itself and

ignore personal motive, while wholly and trustingly surrendering its energies to the cosmic, impersonal impulse, wherever the latter may lead. The presence of a personal motive generates a refractory medium in the mind of the artist, rendering his vision dim and his ideal disproportionate. Motive in art is the Procrustean bed on which Beauty is contortioned into a fixed and ankylosed figure. The artist, be he painter, sculptor, poet or composer, must have the power to rise in contemplation to the formless and boundless, to discard hopes, sympathies, opinions, theories—yea, art itself—while yielding up his very sanity to the ecstatic vision, the impersonal will-impulse, the intuitive perforation. The merest reflective touch, or yielding to the fashioning, computing action of the intellect, at once mars the sublimity and holiness of the word or picture. Hence, while science and philosophy, to their nature are didactive, art can intellectualize and theorize only at the peril of involving self-destruction. The question to be held before the artist is not to what extent shall I succeed in imparting through this painting, this statue, this poem, this song, a power to affect the moral consciousness of the world as I conceive it, but rather, how shall I adjust myself to these divine forces so as to be true and faithful to the task, and able to flawlessly mirror her light in my creation? For while philosophy computes and constructs, and science applies and exhibits, art must serve as a mirror for the rarest light—the light of the soul—the substanceless vision, and therefore be absolutely pure and free. Science is gauged by instinct and intellect; philosophy by intellect and feeling: art by feeling and intuition. The subject-matter of art is intuition, while its discerning power is feeling.

This separation in consciousness between the beautiful *per se*, and the personal and circumscribed qualifications of the mind, as represented by the forms and modifications of reason and intellect applied to art, indicates at once and unmistakably the position which the artist can and must occupy in his field of action. The only legitimate signature by which true art identifies itself with its work, is the disclaim of self-interest and freedom from personal motives. For as an artist —no matter what the greatness of his genius—if still held by his egoism to the limiting horizon of concrete causation and temporal moral imagery, and thus depends for his vision on the light of the probable and appreciable in the passing event—it follows that his knowledge of life in general, and of the human soul in particular (its needs, powers and possibilities), is bounded rather than boundless. And yet, what but the boundless and timeless vision can ever be trusted to dictate or prescribe for the creatures of evolution a course which, with unerring safety, is to complete the circuit of their destiny? Would a gardener, however experienced, trust himself to adequately dole out so much nitrogen, oxygen, carbon, etc., required for each plant to strike the biologic balance of its growth? Or does he not rather trust to the fact that the plant, by virtue of its native powers of absorption and selective affinity, will extract from the soil and air the elements needed for the fulfilling of its specific evolution? How, then, dares the artist—a veritable gardener of the soul—in administering beauty to human life, emphasize any particular characteristic, any conventional and ephemeral aspect of moral principle or esthetic concept, any intellectual code of virtue, any personal lesson in heroism, patriotism, pietism or civic excellence, when beauty in itself, in its own eternal, ever-present, ever-inspiring genius, contains all that is essential and needful for the safe unfoldment of human life and destiny. To arraign beauty in any didactive attitude, even the noblest; to endow her with any attribute, however ethical and exalting, is to crystallize her spirit in a mold of clay, to change her radiant smile into a grinning proxy, to embalm into immovable fixity the impulsive play of life in its cyclic, rhythmic action—in a word, to give permanence and ceaseless perpetuity, as a moral lesson, to a conception temporarily arising in the mind of the artist, only to be followed by innumerable others in the natural course of development, and in response to his continued aspiration. Art is spiritually legitimate only to the extent it is structureless and fluidic, *i. e.*, to the extent it employs symbols in place of con-

crete elements in its representative work. To be true to beauty, and a trustworthy interpreter of her message, the artist must throb unceasingly to the pulsations of highest spiritual life. Type must mercilessly be sacrificed to symbol, technique to movement, posture to rhythm. Form, phase, perspective and general laws of mechanics—however indispensable for the expression and cultural appreciation of art—simply indicate the inadequacy of personal intellectual consciousness to the task of comprehending beauty; the evidence of mental exhausture in the efforts of the artist to respond to, and to interpret—through the play of affirmative, motivized, personalized self-consciousness—the breath and force of magic life, the ethereal touch of the wing of the soaring genius which we call beauty.

For beauty is abstract, form is concrete. To grasp the meaning and genesis of beauty, feeling alone can be trusted to occupy the field of observation. Any impulse tending to abduct the artist from the path of feeling is inimical to true art. To permit intellect and personality to take part in the labors of art is to usher into its sanctuary the conflicting statements of mental judgment, moral discussion, intellectual agitation, etc., in the chaos of which the light of beauty sooner or later becomes extinguished. Accessible only through the tuitions of feeling, art, to become a vehicle for beauty, must spiritualize the mind of its devotees into flights of purest abstraction, uncolored by any sentiments, any attributes, any temporal aim or object, any fear, hope or desire. For the artist is not to materialize the spiritual, but to spiritualize the material; to set wings to the soul, and fire to imagination; to lift the whole human situation, not on a basis of civic interests or ethical application, but by exploring the realm of the unseen, by listening to the unheard-of, by feeling the inexperienced and unknown; to see, to know, to feel the genius of beauty; to revel in its light, and create by its powers; and thus, by opening up sluices of vital harmonies in his soul, succeed in metamorphosing the individual from man to superman. The artist is safer—is, in fact, then only safe—when relying on nature rather than on culture for his guidance and inspiration. The picture galleries of nature exhibit the moral dignity, vital supremacy and simple loftiness of true life—the statuesqueness and elemental power of the mountains, the immensity and spotless purity spread before us in the ocean; the innocence and vital graces made living and impressive in the animals; the touching beauty and loveliness enchanting us in the flowery world, etc., are all means and methods by which nature, through an exalted symbolism, aims at overcoming the impediments of type by stimulating the human imagination to transcend the sphere of form.

It was not from failure to understand the moral value of the useful that gave to Kant the notion of separating in his mental categories the element of beauty from the element of the useful. With intuitive keenness he recognized that the support of the concrete world has not its basis in the beautiful, nor is the latter an outgrowth or expression of the useful; but that beauty has its aim and object in recalling to our minds an immortal and divine existence.

And as feeling is the faculty that enables us to communicate with the beautiful, it follows that the field of life where the greatest opportunities are offered for the unfoldment of true art, is found in the realization of individual self-consciousness. Before I can know the feelings of my fellow-creatures, and become capable of describing them, I must acquire a knowledge of my own; and this phase of knowledge, when expressed in descriptive art, is called lyric poetry—the only poetry which is at once imaginary and real, at once truth and fiction. It is the description of life itself, as found to well up in the unceasing changes of consciousness, detected and portrayed by the power of individual feeling. And thus, while the didactive, *i. e.*, the intellectual, reflective poetry of Alexander Pope, who once put a game of chess into rhyme and meter, possesses no other survival value than that of an ingeniously elaborated philosophical or ethical treatise, the lyrical poetry of Burns, Byron and Shakespeare with their immense, all-swaying individual feelings, by which they gained knowledge of the

deepest springs of human nature, will never cease to exert a powerful influence over the hearts and feelings of men. Lyric poetry suffers no social contracts, no standards of conventional moods, or modes of form; is not confined to the succession of time, or the limits of space; it spreads its wings over centuries and ages, imparting duration to the sublime moment in which man rises superior to the pains and pleasures of life. Under the spell of the lyric poet we dispense with the measuring, calculating and circumscribing conception of life, as we rise to the horizon-free vision of beauty in its native, transcending grandeur and holiness. Soaring in the motive-free regions of pure feeling, we forget the tumult of earth in listening to the swelling harmonies of liberated soul-life. Existence, with its strife and strain, recedes into the calm, passion-free symbolism of impersonal, evolutionary vital processes.

Only through the power of feeling can beauty be determined. The form, as such, which largely appeals to our intellect, can only with uncertainty convey to us the beautiful. To the eye of feeling and to the eye of intellect the world presents diametrically different aspects. Often what the intellect admires, the feeling passes by with indifference. Often the ruins of structures and monuments give rise to stronger emotions and nobler thoughts than a newly-erected architectural masterpiece. What are the structures of modern building-craft, with all their elaborate and motley adornment of luxury and brilliancy, when compared with the crumbling fragments of ancient ruins—the segment of an arch, or a few broken-down columns—if measured by the soul-heaving and exalting emotions conveyed to the reverent beholder? "Perhaps," says Madam Stael, "that a masterpiece of art in all its splendor can not impress us with such grand ideas and aspirations of beauty as its own ruins. * * * Beauty is of expression, not of form."

It is to be understood, however, that the beautiful is divorced from the useful only on the plane of the concrete and ephemeral. Applied to the eternal part of the individual, the beautiful possesses a usefulness which involves issues so sweeping and far-reaching that the rise and fall of solar systems form incidents in its career. Ultimately considered, it is in the object of beauty that the usefulness has its greatest significance, revealing, as it does, the powers and potencies in the individual soul by which the key is given to unlock the mysteries of both animal and divine nature. Beauty is the signature of truth, and it is truth that shall make us free. Through beauty our interests expand from the needs and necessities of the body to the needs and necessities of the soul; from the usefulness of physical evolution to the usefulness of spiritual evolution. On the wings of the beautiful the soul of man rises himself from Earth to Heaven.

Obstetrical Case—Arm Down and Head Behind the Shoulder.

BY C. D. R. KIRK, M. D.,
Shuqualak, Miss.

I was called to assist Dr. J. D. Kellis, of this place, in delivering a woman who had an arm down, the Doctor having found that there was too much for one doctor to do. The patient was a small negro woman who had several children. The child was most thoroughly packed, and it was with the greatest effort that a hand could be inserted in any direction. We administered an anesthetic, and, after several failures, a hand was made to pass with palm to the child's back, and succeeded in ascertaining that the head was back of a shoulder and the neck stretched to a very small size. We undertook to dislodge the head by pushing it up, and at the same time a steady pull of the presenting arm, but failing in this, we made another effort to reach a foot, and, after an exhausting trial, with palm to the back of the child, a foot was reached, but not until operator's hand was so much exhausted and cramped that he could not grasp the foot with sufficient strength to disengage it; therefore, the blunt hook of a Hodge forceps was made to follow the hand to the child's foot, and made to grasp it near the ankle; then, by zigzag motion and at the same time

strong pressure on the child's presenting hand, it was turned and delivered by the feet. The uterus closed down nicely, and some stimulant revived the patient, but she died in a few hours of exhaustion.

In a long practice the writer has seen but two cases of this kind, viz., arm presentation with head behind the shoulder. The other case was a large, roomy woman, and, therefore, the child not so thoroughly packed, but all such cases are very difficult to deliver, and will test the doctor's skill and physical strength.

Perversion of Phosphates.

BY J. M. ADAMS,
Biological Chemist, Watertown, N. Y.

The American haste in eating is raising great havoc with digestion. It is hardly worth while to give a warning, for people will not heed anything said on this subject. It is not anything new, for all doctors are well aware of the fact. The strangest part of all is that doctors themselves are often so hurried as to take as little time in eating as possible. It is one of the worst habits to regulate and control of any formed, for it follows the very nature of the individual, and is a part of his make-up. The hurry is on, and nothing can stop it. The stomach must take care of itself, no matter what follows.

A greater damage comes from intestinal fermentation of granular nuggets of starches or grain foods in lumps, which if unchewed as fine as flour, will, as soon as they reach the intestines, become fermentative in more or less degree. The slightest fermentation will cause a like precipitation of phosphates from the food, and right here becomes the trouble that affect so many.

As an experiment, suppose we have a clear solution of phosphates in a tube and add thereto a drop of ammonia. The consequence is a white precipitation of ammoniacal phosphates. The fermentation caused by undigested starches affords just this condition in the intestines, and down goes the phosphates, so strong sometimes as to fill the intestines with crystals that cut like powdered glass. The same thing occurs in the urine also, although not quite so direct. These partially precipitated phosphates are also taken up by the lacteals and carried into the blood and finally become lodged more or less, causing phosphatic granulation disturbant rashes, rheumatism, paralysis, kidney irritants, bladder irritants, and all sorts of ailments which result in diseases of nervous system, the bony system, brain, heart, and all sorts of results almost too numerous to mention.

A large part of insane inmates are hoggish eaters. They always swallow foods in lumps, scarcely chewed. The consequence is a robbing of the nervous system of its proper nutriment by a precipitation of phosphates, which become a disturbing cause rather than a feeder of the nervous system. They are thrown into the intestines and kidneys, because not kept up in a solvent form. They become arthritic, terribly disturbed, wild and furious. Nearly all rheumatic cases nowadays are phosphatic. The perversion of phosphates in the system is ruinous in youth as well as in old age.

Children should be taught to eat slowly and chew finely. Elementary school books should insist on this being done. We can not have a healthy and well-developed people without it. "Phosphatics" are always scrawny, thin, lank and lean. The dyspeptic lines from mouth and nose are always indicative of the disordered digestion. Not only are the starches fermentative but the acidity sometimes in the stomach is enough to change them into glucose or partly that way, so as to cause a diabetic tendency, if not the real disease. The sourness of the stomach further changed by acidity of the sugars often makes the whole food in the stomach so sour as to neutralize the pancreatic fluids (which are alkaline), and thus the fats are not emulsionized, and a consequent leanness results. This precipitation of the phosphates is an all-important subject which might be carried further, but enough for the present.

[Written for the MEDICAL BRIEF.]

The Practice of Homeopathy.

BY N. SISCA, M. D.,
Killarney, Queensland, Australia.

(Continued from page 138.)

IX.

The question now arises: Is it claimed for the principle *similia similibus* that it holds good in every case? No. Homeopaths frankly admit that it has limitations, and the late Dr. R. Hughes, whose writings have done so much for homeopathy in Great Britain, in his "Principles and Practice of Homeopathy," says: "Where your patient's trouble is one which drugs can not simulate on the healthy body, you can not apply your law. How can drugs produce anything like the disorder of sensation and function attending the passage of a calculus? How can they supply analogues to neoplasms?" Further on Dr. Hughes says: "Cold baths in typhoid; hyposulphite of soda for preventing the recurrence of relapsing fever; full doses of iodide of potassium in tertiary syphilis, of opium in peritonitis from perforation, of digitalis in cardiac dropsy, nitrite of amyl in the paroxysm of angina pectoris—even venesection when necessary in uremic coma, are instances of treatment on which homeopathy can hardly improve."

On the other side of the Atlantic Dr. Preston Sutherland, of Boston, in his presidential address to the American Institute of Homeopathy (1904), said: "Is there any one calling himself a homeopathist today who will claim that the use of a drug alone, administered along the line of similars, will cure every diseased condition as quickly and surely as any other means known to the medicine of today can cure it? Is there any homeopathist today who claims that he can select a drug under the law of similars which will achieve the results of fresh-air treatment in tuberculosis, of surgery in pathologic conditions requiring the knife, of saline injections in collapse of diet in diabetes, gout and scurvy, of thyroid extract in myxedema, of psychotherapy in certain neuroses, of suggestion in hysteria, etc.?"

Those, then, are the acknowledged blanks and limitations of *similia similibus*. For the rest, homeopaths say no case of disease which is at all amenable to the influence of medicine can be said to be outside the sphere of its dominion. Is it all true? Can it be all true? We can not say yes or no until we have tested it.

And now a word as to the value and the importance of symptoms in the practice of homeopathy.

It is often alleged against homeopaths that they are mere symptom-treaters, but let us see: To begin with, we must not lose sight of the fact that, as I have said more than once before, homeopathy is essentially and exclusively a method of drug treatment, a method, that is, of applying drugs to the treatment of disease. Its reign, therefore, begins and ends with treatment, but the treatment which homeopathy advocates presents the distinguishing feature of being based on the study and interpretation of three different sets of symptoms. Homeopathy goes hand in hand with allopathy from anamnesis to prognosis, but when it comes to treatment, then the best and most important half of the homeopath's task begins, because then he has to diagnose his remedy, a single remedy, which must be the nearest possible approach to the *simillimum*, the one, that is, which will cover the totality or at least a large majority of the symptoms. And this he can only expect to be able to do by mastering the whole symptomatology of the case, viz.: 1. Objective symptoms, or, as we call them, physical signs. 2. Subjective symptoms, as described or complained of by the patient. 3. Drug symptoms, or those belonging to the drug, of whose pathogenesy the objective and subjective symptoms of the case in hand are the most approximate reproduction. In order to make this clear, let us see, for instance, how a homeopathic physician would, or, at all events, how I think he would, treat a case of ordinary colic.

He would first of all satisfy himself as to the origin of the colic, whether brought on by a chill or by indigestible food, etc.

Next, he would notice whether the patient has hiccough, whether he is very intolerant of pain and inclined to be snap-

pish, etc., and then he would proceed to question him as to whether he is constipated or has diarrhea; whether the pain is worse at night; whether the hot applications he most probably has used have relieved the pain, or, perhaps, made it worse; whether the pain is relieved or not by bending double, or else worse by bending double and better by straightening the body out; whether the pain begins at the navel and radiates all over the abdomen; whether, perchance, he feels as if his belly were full of sharp sticks or stones, etc.

After this the physician would examine the abdomen to see whether it is tympanitic or relaxed, or else retracted to the spine, and to feel by palpation whether the abdomen is sensitive to touch; whether the transverse colon can be felt distended like a pad, or if there is a spot which feels as if grasped with the nails, etc.

Finally, and as quickly as his knowledge of the *materia medica* enables him to do, our homeopathic confrere would mentally make his drug diagnosis and prescribe or dispense the medicine, as the case may be. Of course, there would be no objection to the use of warm applications, if not contraindicated, and if the exceptional severity of the case made it imperative, even an injection of morphia would be resorted to, but homeopaths, as a rule, have very little confidence in morphia, and never resort to it unless literally compelled to do so.

If we now take the principal drugs, which have colic in the adult as one of their symptoms, in their alphabetical order, the process of mental drug selection would be somewhat like this:

Colic from a chill, great mental and physical restlessness, no position relieves —aconite.

Incarcerated flatus at a spot which feels as if grasped with the nails, transverse colon protruding like a pad, abdomen extremely sensitive to touch, even of bedclothes—belladonna.

Pain worse at night, flatulence, great intolerance of pain, worse by hot applications, patient inclined to be snappish and spiteful—chamomilla.

Pain worse at night, flatulence, nausea, depression, abdomen feels as if full of sharp sticks or stones—cocculus.

Pain agonizing, relieved by bending double—colocynth.

Pain begins at navel and spreads all round, worse by bending double, better by straightening body out—dioscorea.

Colic, with diarrhea, from exposure to damp cold—dulcamara.

Pain greatly relieved by hot applications, much belching of gas with no relief —magnesia phosphorica.

Colic, mostly associated with obstinate constipation, abdomen retracted to spine as if drawn by strings—plumbum.

Colic accompanied with hiccough—veratrum album.

But that is not all. Should the abdominal pain or soreness turn out to be the recent or remote after-effect of a bruise, all the above drugs would not "be in it" at all, and the remedy would be arnica. Or if the pain recurs with clock-like periodicity every day or every other day, and so on, the remedy would probably be cedron, etc., etc.

Taking now the above as a fair specimen of homeopathic practice, what is there in it to justify us in saying that homeopaths are mere symptom-treaters? If anything, there is evidence in it of the fact that the homeopathic physician examines his patients more minutely, listens to them and questions them with greater patience and more painstaking completeness than most of us deem it necessary to do. It is undoubtedly true that the importance of symptoms in homeopathic practice is paramount, but that is only in keeping with the fact that from the time of Hahnemann to the present day, homeopathy has always taken the clinical aspect of disease as its working basis, giving, of course, its due to pathology so far as its importance for diagnosis is concerned, but maintaining all through that for drug therapeutics on the homeopathic principle symptomatology must supersede diagnosis. Only it is not this or that other individual symptom that decides the selection of the homeopathic remedy, but the totality of symptoms; that is, the totality of the phenomena exhibited by the entire organism under the influence of disease. One or two instances will make this clear:

Some few years ago a patient suffering from some lesion of the nervous system

which gave rise to the phenomena of progressive muscular atrophy, and whose case was said to have been pronounced incurable, and probably fatal by allopathic neurologists, consulted the late Professor T. F. Allen, of New York. Ignoring, so far as treatment was concerned, all the learned opinions which had been put forth relative to the pathology and prognosis of the disease in hand, Dr. Allen approached the case more homeopathico, and as the totality of the symptoms suggested phosphorus, phosphorus was given, and it cured the patient.*

On one occasion a certain physician of Albany, New York, was called in consultation on a supposed case of phthisis pulmonalis. After carefully examining the case, he was asked: "What is your diagnosis, Doctor?" "Stannum," said the Doctor. "What?" "Stannum," he replied. Stannum was the diagnosis of the remedy, not the disease. Stannum was given, and cured the patient.†

That, then, is the position taken up by homeopathy. "Pathology," says Dr. Hughes, "has taught us to recognize enteric fever as specifically distinct from typhus, and for many purposes this differentiation is highly important, but the indications for its homeopathic remedies were just as plain when it was classed as typhus abdominalis."

Pathology, says the homeopath, is good for diagnosis and prognosis, but symptoms, especially the subjective ones, are the basis for treatment, or, in Hahnemann's own words: "The totality of symptoms, this outwardly reflected image of the inner nature of the disease, must be the chief or only means of the disease to make known the remedy necessary for its cure."

And, as if to re-echo Hahnemann's words, Dr. Rose Bradford, in the "Purvis oration," delivered at Greenwich (England) in December, 1904, said: "The importance of the thorough study of symptoms must be at once granted when it is remembered that in a large number of functional diseases symptoms only are present. In many functional diseases the remarkable character of the subjective sensations complained of by the patient afforded a clue to the differentiation of the malady from organic diseases, with which it might at first sight be confounded. * * * Whether medicine is regarded from the point of view of diagnosis, prognosis or treatment, it is most important in all cases to pay great attention to the study of symptoms, if success is to be achieved."

And such, as briefly, and also, I greatly fear, very imperfectly and disconnectedly, I have endeavored to sketch it out, is the practice of homeopathy, governed and upheld in all its omissions and commissions by its great principle, *similia similibus curantur*, founded chiefly, but not solely, on the study and the interpretation of any and everything that deserves the name of a symptom, and on the correspondence between all the symptoms of any given case, and the "pathogenesy" of the drug, or the symptoms produced on the healthy by the drug, which has any claim to its being the remedy for it.

A Short Article on the Subject of Circumcision.

BY A. L. HODGDON, M. D.,
Pearson, Md.

It would seem that some of the medical profession are opposed to the operation of circumcision, apparently considering a foreskin covering the glands to be beneficial to the individual possessing one. I think that the person who has been successfully circumcised is, after the wound has healed, in a much better condition than the one who has his glands covered with a foreskin, as the circumcised man has an uncovered gland free from unpleasant smegma. If a man has been circumcised so that the glands are uncovered, and can not be made to remain covered, and considerable of the internal mucous lining of the foreskin remains back of the glands, I think he is in much better condition after the parts have healed than one who has his glands covered with a foreskin, with possibly considerable unpleasant smegma under the foreskin. I have performed circumcision many times.

Irritations of the Respiratory Mucous Membrane.

BY EDW. C. ROTHROCK, M. D.,
Palestine, Texas.

Where there is irritation, an engorged condition of the respiratory mucous membrane, an exhausting, hacking cough, remedies to allay the irritation, relieve and give rest to the patient, are called for. Morphine or opium will give relief, but other remedies will be mentioned in this article in connection with this condition. In acute inflammatory conditions of the respiratory organs, as bronchitis, laryngitis, penumonia, etc., remedies must at first be used to reduce the hyperesthesia of the bronchi, alveoli, etc., as the case may be, and throw off the inflammatory condition existing—remedies not only to allay inflammatory action, but to enable the mucous membrane to secrete and throw off the morbific products. The frequency of throat and lung troubles, and their serious nature, make the subject of treatment of the greatest interest. In such cases inflammation often spreads rapidly by continuity along the bronchial mucous membrane until the lungs, small tubes, alveoli, etc., are involved, constituting pneumonia, broncho-pneumonia, capillary bronchitis, etc. Such conditions frequently occur, particularly in children, in whom the structure of these organs is very prone to quick inflammatory action and extension of that action. The bronchi becomes plugged with mucus which, in young children, is not expelled, which may lead to collapse of adjacent areas of lung and extension of the disease and embarrassed respiration. In the early stage the physical signs may be, and often are, masked, and, therefore, the diagnosis is frequently not made until the disease is well advanced. The early recognition of the grave nature of such troubles and prompt measures of treatment, both medically and to sustain the vitality of the respiration and the circulation, are important. The elevation of temperature will often aid us to form a proper diagnosis frequently when the physical signs are not recognized. These signs vary greatly as to location and extent of involvement of the pathological process.

The fine râles heard on deep inspiration frequently escape notice, but respiration will always be accelerated and often labored, and as the disease progresses, dyspnea, high temperature, dilation of the alæ-nasi, recession of the soft parts on inspiration appear. These symptoms are more marked in children. Prostration is often present, even in the first stage, and will indicate the treatment to maintain the vital forces. As to treatment, the first consideration is the respiratory function, to clear out the irritated bronchial tubes by prompt liquefaction and expulsion of mucus, and in infants prevent its absorption. The free access of pure air to the diseased parts will be of the greatest advantage. The air of the sick room should always be as sweet and pure as ventilation can make it; windows should be opened at the top. Draughts are to be avoided, of course, and an equal temperature should be maintained. The respiratory tract must be kept free and clear as much as possible. In children the nostrils are often plugged up by secretions which collect in these parts and often embarrass the breathing. Vaseline inside and outside the nostrils frequently is of use and effectual. Free irrigation with a warm alkaline wash, as a half-teaspoonful of bicarb. soda, or the same amount of borax or of boric acid to teacup of warm water will be effectual in relief of the occlusion. In young children under four or five years, there is very little expectoration, if any. The mucus that collects in the bronchi and sometimes coughed up should be removed by the fingers of mother or nurse, and not allowed to be swallowed; this will be of great relief. The respiratory muscles are weak, and the walls of the chest are soft and yielding, and the movements of the thorax in the act of respiration very easily become embarrassed in young children when mucus is allowed to collect in the bronchial tubes, and is not expelled. The muscles of respiration are greatly impeded, often causing congestion and collapse of areas of lung. Atalectasis is collapse of lung. Air vesicles become clogged and exclude air, the plug gets out, but air can not get into the acini, and collapse follows.

Ammonia is a valuable agent to clear the bronchi; the carbonate or muriate is very useful; the carbonate of ammonia, one to two grains given in syrup or milk every one or two hours, according to urgency of the case, and would not be too much for a child one or two years of age. Aromatic spirits of ammonia is a nice preparation, and could be used in doses of ten to twenty drops, water two ounces, teaspoonful every hour or two. We get the stimulation of ammonia and its expectorant effect. The syrup of ipecac is a good old remedy. The wine of ipecac is also good in doses of one to two drops for young children. The acetate syrup of sanguinaria in doses of five to twenty drops, according to age of child, every two hours, is prompt to relieve. Sanguinaria is a valuable remedy, and in croup is near specific; in penumonia it is very useful; in chronic nasal catarrh, hypertrophy of nasal mucous membrane by insufflation, it is curative; in acute or chronic bronchitis and asthma it is prompt to relieve and cure. It is an excellent tonic expectorant. It is an excellent expectorant in small doses of the sanguinaria, one-eighth to one-sixteenth grain for adults, and can be used in place of the syrup. But for children the syrup is preferred. Temperature is often high. 105° F. and over; to reduce heat, aconite, one-quarter to one-half drop should be given to children one or two years old, every hour or two, as indicated until temperature abates, then every three hours. Aconite should be used with care; it has a selective action on heat centers, and is one, if not the best, of medicaments to overcome inflammatory action. For adults aconite, spec. tinct., one to two drops, is the dose. Some could take more, but small doses have better effect. Aconite has been called the "therapeutic lancet." A lethal dose produces great muscular weakness, irregular and labored respiration, slow and weak pulse coldness of the surface, clammy sweat, tingling in extremities and lowering of body temperature. Death is from paralysis of the heart and respiration caused by relaxing of the inhibitory apparatus of the heart, hence paralyzing the cardiac ganglia, the spinal cord and respiratory functions.

Counter-irritation to the chest is very useful, as mustard; a warm mush poultice with turpentine upon it and applied over the chest is of great benefit, and should come up well on the neck. A flannel well soaked in tallow, sprinkled with turpentine, applied warm and allowed to remain for a day or two, is good. I have kept such plasters on for days with much relief to patient. It has a tendency to draw the blood to the surface from engorged parts; keeps the skin moist, and at a uniform temperature, relieves pain, and greatly adds to the comfort of the patient. A constant cough disturbing the patient is relieved by breathing warm, moist air; a vessel containing warm water and a few drops of turpentine, is good; so is camphor in the water, or used as an atomized inhalant. It is very agreeable to the pulmonary organs, and could be used every three hours. Codeine, one-fifth to one grain for adults, for children one-thirty-second to one-sixteenth grain, as to age, is very valuable in irritation of the bronchi, where there is a hacking, teasing cough. It is less constipating than opium, and no doubt but what it has a selective sedative influence on the pneumogastric nerve.

A supporting treatment in disease of the respiratory organs will nearly always be needed in children from the first, and, indeed, frequently in adults. An easily assimilable nourishment must be used; sweet, fresh milk, rice, raw or partly cooked fresh eggs well beaten, or very soft boiled eggs and meat broths.

Therapeutics of Collinsonia.

BY WM. I. MOORE, M. D.,
Kingsland, Texas.

Will you please, in some issue of the BRIEF, give us a write-up of the therapeutics of collinsonia?

[We call on our readers to let the Doctor, or whoever else may be interested, know what collinsonia will do, more than the dispensatories say in regard to it. The American Dispensatory seems to give, through Professor Scudder, a pretty fair statement of its virtues.—ED.]

[Written for the MEDICAL BRIEF.]

Constitutional Effect of Idiopathic Epilepsy.

BY PATRICK T. MELDON,
An Experimental Medical Scientist.
San Bernardino, Cal.

This patient, at the time of treatment, was thirty-three years of age and the mother of five children. One child, a boy, inherits her disease, in the procursive form.

Her first attack of epilepsy came on when she was three years old. She was married (advisedly) when she was fourteen years old. Soon after her marriage her bowels became torpid, and a little later ulcerated; medical treatment kept her bowels relieved from time to time.

Her epileptic spasms averaged about fifteen per week, but they were not the characteristic convulsive spasms of true epilepsy. She would simply drop and as it were go into a deep, placid sleep, and remain in it from one to three hours; relaxation of every muscle and fiber then took place, congestion and hemorrhage of the left lung being prompt, and uterine hemorrhage closely followed. In that way the patient had often flowed for several consecutive days.

Five years ago the constipated and ulcerated condition of her bowels refused to yield to medical treatment, and she was medically advised to leave her home (in Ohio) and go to California. This advisement did not have the desired effect; the septic condition of her bowels got worse after she came here, and the best physicians afforded her only nominal relief. In my investigations of various supposed incurable diseases, her case, as an epileptic, came to my notice. She was indifferent about giving me the history of her epileptic affliction, but she was anxious to know if I could relieve the condition of her bowels. This condition, having bested so many physicians and treatments, seemed to justify me in making an experiment, so the following was tried in her case:

℞ Precipitated Sulphur.....2 ounces.
Pd. Myrrh.....1 ounce.
Pd. Aloes..... ½ drachm.

M. Sig.: One-half to one teaspoonful once or twice a day after eating. Irrigated the bowels freely once a day, after evacuation, with one-half of one per cent solution copper sulphate.

This prescription cured the ulcerated and constipated condition of her bowels in about twenty days. A cure of the ulcers was expected from the start, but a permanent cure of her constipated condition—such as has been effected—was not expected. At least, her bowels have been acting with perfect ease and regularity during the past year and nine months, or since she took the treatment.

Two months after this treatment she complained to me of soreness across her abdomen; she said she had been troubled with it for several years. As most all epileptic patients have a feeble circulation and a cool skin, that was taken into consideration. On examination her skin was found cool and her pulse rate fifty-nine beats per minute;. this indicated feeble sexual power. When closely questioned she said she always had to strain herself in copulation; and in most cases—even after severe straining—she would fail in her function, and, physically exhausted, have to abandon the effort. When she would accomplish her function, flooding would usually result, yet, regardless of the result, she was always anxious for complete copulation.

For this affection I gave her two drachms of tincture cantharides, two ounces powdered cubeba, and directed her to take three drops of the cantharides on about eight grains of the cubeba three times a day. In six weeks on this treatment her pulse rate went up to seventy-two beats per minute, the abdominal pains had left, copulation was successful without effort; and only two epileptic spasms—both within ten hours of each other—but they were evidently very slight in the absence of either lung or uterine hemorrhages. The patient was delighted with what good the treatment did in her case, but I regret it should have done much mischief as well. She was, to all appearance, a plain, very reserved and modest woman before the treatment, but now nymphomania has plainly set in. She plainly told me that which surprised me as the result. It seems as if she could not control the sudden awakening from her long torpid condition. She plainly and boastingly told me that she had, as the result, violated her marriage relation and added, "If he don't like it" (meaning

her husband) "he can hit the high places." I listened to her attentively, and when she asked to have her treatment renewed. I turned on her with a storm of evil abuse and sent her away trembling and tearful.

She has returned several times since then, requesting me for the treatment, and stating that her sexual nature has gone back to what it was. But her spasms are still very few and only of about twenty minutes duration. She says that my treatment for her sexual weakness was curing her epilepsy, but I know that it was only reducing it by curing its constitutionally ill effect, yet, am I justified in denying her the treatment?

[Written for the MEDICAL BRIEF.]

The Treatment of Lobar Pneumonia.

BY ROBERT C. KENNER, A. M., M. D.,
Louisville, Ky.

Careful attention to all details is necessary to success in the treatment of pneumonia. The most scientific treatment, coupled with good nursing, will fail if details are not given attention. In all cases it is highly important that the room in which the patient is confined shall be ventilated properly, and that the temperature is kept at the correct mean. The temperature should not be allowed to go above 70° F., or descend below 65° F. On the one hand a high temperature will be oppressive, on the other the low will prejudicially affect the patient, and he will suffer discomfort or probably contract other diseases.

Stimulants are useful in the treatment of pneumonia, but their routine employment is highly prejudicial in many instances. In any case where they are not called for they are worthless. In cases where they are indicated, I know of no measure capable of rendering greater good. Alcoholic stimulants are vastly superior to strychnine. In fact, strychnine is valuable, but not suited to a case where stimulation has to be maintained for a period. In instances of threatened heart failure strychnine is valuable, but alcoholics are more useful when the effect of a stimulant has to be maintained for a greater or less period. In no instance is it necessary to administer a stimulant to sthenic cases. Here, as already said, they are worthless, but in asthenic cases they are indeed "oak and rock." I feel sure that I have carried many patients through critical phases of pneumonia who otherwise would have succumbed to the affection. Jurgensen is truly one of the greatest observers that has adorned modern medicine. He is confident that stimulants are responsible for the recovery of cases that would otherwise rapidly sink. He therefore wisely advises that stimulants be given in such quantities and in such dosage as will keep the pulse volume full and regular. If large quantities are necessary to attain this, he gives the required amount. He thinks that one who is too cowardly to carry out this principle ought not to be trusted at the bedside, where a life may be lost by lack of intelligence and fortitude. Diet is an important matter. It is a mistake to give too much food. Milk and light foods easy of digestion and assimilation are called for, but in a great many cases more harm than good will be effected. Forced feeding—except in asthenic cases—is not to be thought of. If the patient is allowed to eat ordinary foods, such as meat, bread and vegetables, we will find him suffering very often with indigestion that may beget colic, flatulence, insomnia and other conditions that will prejudice the chances of recovery. Milk and water, soft-boiled eggs, vegetable soup and toast are all the foods I allow. These are adequate, and cause minimum digestive trouble.

For the first week there is generally more or less pleurisy, and as the pain and restlessness are due to this cause, they are factors of no little concern to the attending physician. The pain must be relieved. Often this can be accomplished by application of an anodyne liniment. But in a great many instances only an opiate will be effective. Dover's powder is an agent that has found favor with several generations of practitioners. It can be given to an adult in doses of ten grains, and instructions are to be left with the nurse for it to be repeated as often as is necessary to bring comfort to the patient. Ten grains every six hours are usually sufficient to insure rest and exemption from pain. Blisters are employed by many

able physicians in this country and Europe. My friend, Dr. P. C. Sutphin, thinks them very valuable. They relieve the pain in many cases, still they interfere with examination of the chest, and are opposed by many patients, and I do not frequently use them. Poultices cripple the respiration by their weight, and may work much detriment. The encasement of the chest in cotton batting, etc., confines the heat, and often greatly annoys the patient, and I am not able to see any benefit they confer. It is unwise to allow these patients to exert themselves. Allowing a patient to get up out of bed, or sit up in bed, when he has a fever, unduly taxes his strength, and does material harm. Often cardiac failure is a result of this indiscretion.

The sulphate of quinine, in my hands, has proved a remedy of great value in the treatment of lobar pneumonia.

Its action I am not able to explain, unless it be that given by Shoemaker, who says: "As quinine checks the principal phenomenon in inflammation and suppuration, which is the escape of the white blood-cell, and, by preventing the exchange of oxygen by the red blood-cells, reduces inflammation, it is especially serviceable in pneumonia and other localized inflammation and also in reducing discharge from abscesses and preventing sapremia or pyemia." I begin with the administration of the sulphate of quinine in doses of five grains, and continue it until febrile action has ceased to be a factor, and that resolution is practically complete. This drug hastens resolution, and I regard it as the best remedy we know, and, in fact, it is the only drug which exerts what may be truly termed a curative action on the disease process. When the quinine produces much tinnitus aurium, I give the bromides in doses of fifteen to twenty grains. This speedily dissipates this symptom.

When resolution is tardy, we should suspect some associated morbid action. This will be found. But in some instances it will be found that indigestion, restlessness, pain and other symptoms or transient disorders will be found responsible. Failure to relieve the pain associated with pleurisy will greatly protract resolution. In every instance, however, there is some factor that is responsible for tardy resolution, and it must be carefully sought.

It is a great mistake to give a patient drastic cathartics. These lower the resisting powers by increasing debility. I correct the constipation with mild laxatives—but never carry even these to the point of depletion.

It is greatly to the advantage of the patient to give him a tonic. A preparation containing the extracts of cod liver oil, or an emulsion of cod-liver oils is of great value.

[Written for the MEDICAL BRIEF.]

Those Bible Myths of Eden.

BY J. W. LOCKHART, M. D.,
St. John, Wash.

I have been much interested in some contributions to THE MEDICAL BRIEF on the "Bible Myths of Eden." So far as I am personally concerned it would be far easier to believe the so-called myths than to give credence to the arguments produced to show the mythological character of the Bible narrative. That the creation of the world and of man's advent into it are surrounded with unfathomable mysteries is accepted as a part of my theological belief. I have an unbounded faith in the statement that "In the beginning God created the heavens and the earth." I also believe that the laws which control the universe are a self-existent, integral part of an Infinite Being. Believing this, it requires no great stretch of imagination to conceive that such a God, operating through the laws of his own nature, could create an animal and call it man, or Adam, as it is found in the original Hebrew. The assertion made by one of the writers in the BRIEF that the "Ancient Adam was not a man or male of the human species, but, rather, a mythical being representing the ancient Egyptian Goddess of Death, Atum, or Atoum," is so much at variance with the best authenticated Egyptian history as to deserve more than a passing notice. If such acknowledged authority as Professor Rawlinson may be relied upon, Tum or Atum was simply one of the numerous Sun-gods worshiped by the Egyptians at different periods of their history. He is also styled

"the maker of men," "the universal Lord," "The Creator God," and "the Lord of created beings." He is nowhere mentioned as either a God or "Goddess of Death." Again, Rawlinson says: "Net, Nat or Neith, according to the Greeks, correspond to their Athene, and was thus a personification of the wisdom or intellect of God. She was also known by the title of the Great Mother, which would seem to imply that she was essentially a Nature goddess, not very different from "Maut." It is certain that it was from "Neith" and not from "Aten" that the Greeks derived their word Athene. Aten was simply another of the numerous sun-gods of the Egyptians, and worshiped under the form of a large circle. There seems to have been nothing very peculiar in his worship except that at one time he seems to have been an important rival to Ammon-Ra. He was soon discredited.

"Athor represented the lower hemisphere, from which the sun rose in the morning, and to which he sank at night; but, in the course of time, came to be regarded as only one of the many divinities of the lower world, to be adored together with Osiris, Isis, Horus and others."

"Isis, in original conception, did not differ much from Athor, with whom she was sometimes identified by the Greeks. She was called the mother, as well as the wife and sister of Osiris." Osiris was, originally, a personification of the divine goodness, but came, in time, to be regarded as a form of the sun, the great deity of the lower world, or Hades. His chief office was to judge the souls of men when they entered the lower world. Ammon was the chief god of the Egyptians, the "god above all gods, the king of all gods." Maut, "the mother," was the wife of Ammon, and represented the passive principle in nature. There is no valid evidence whatever that she was ever worshiped in any sense by the Hebrews.

If we may trust to our best dictionaries, philologists do not attempt to trace the origin of our word, Mother, further back than the Anglo-Saxon word, moder. They tell us, too, that our English word "woman," is derived from the A.-S. word, wifman. Why Dr. Morgan has not enlightened the makers of our dictionaries on these points is a mystery to me. Again, the Doctor says: In the Bible we find evidence of her (Mut-Khora), worshiped by the Jews, in the Golden Mice that were carried with the "ark" and in the temple to soften this goddess' anger against the people. If the readers of the BRIEF are really interested in knowing how unfair, not to say palpably dishonest, the Doctor can be, let them turn to the sixth chapter of First Samuel and read the account of the golden mice as there given. They were put in the ark along with the emeroids at the instigation of the heathen Philistian priests, and there is not the slightest evidence that they were ever preserved and worshiped by the Hebrews. In Isaiah we learn (chapter 66, verse 17) that mice were an abomination, an unclean thing, with the Jews. It seems to me that we can gain nothing by attempting to overthrow the statements of the Bible, either by bold assumptions or by resorts to the uncertainties of ancient mythologies. Every year, almost every day, the modern discoveries in Babylon, Assyria and Egypt are establishing, beyond cavil, the truth of Bible history. Again, the Doctor says: "The Womb-Man was the Bible's pleasure garden; man's pleasure garden." That statement is next to preposterous. Learned scholars tell us that the Hebrew word "Eden," meant delight, and was to be a place of perpetual delight for the Adam; for God called their name Adam. In the Hebrew, Adam simply means man, while ish is the word used of man in the sense of husband, and ishshah of woman, in the sense of wife, and neqebah, in the sense of female. It seems strange that any one could even claim to find any connection between these names and the names of heathen deities, much less that they could find any reason for connecting the "delights" of the garden with the sexual pleasures. We are told that God commanded the first pair "To multiply and replenish the earth," some time before they were driven from the garden, and it is unreasonable to suppose that this command was not a permission to enjoy the sexual pleasures while they were still in the garden. Our word womb is the same old word that the Anglo-Saxons used to indicate the belly, or abdominal cavity, whether of the male

or female, and then had no sexual meaning in it. The very distance which some far-fetched arguments find it necessary to travel is a discredit to them.

Now, as to the allegorical story of Eve's temptation. As to whether God created Adam out of the dust of the earth, or whether He created a single primordial germ, or ten thousand of them, and developed Adam from the best of the lot, is of little consequence to us. We must assume that if God created man, or had anything to do with his creation, the result must have been a perfect and holy being. Then comes the question, Why or how do we find man in his present deplorable condition, as compared with his former state of purity? All the philosophies and religions of the world, as far back as we have any record, recognized the two principles of good and evil as existing in the human heart, and with none was the belief in the principles of good and evil so distinct as in the Hebrew mind. With most, if not all, the nations of antiquity the serpent was regarded as a sort of incarnation of the evil spirit, and we are told that it was "that old serpent, the devil," that tempted our first maternal parent. Now, it matters little to us whether the serpent talked to Eve in the Hebrew tongue, or whether in the still, small voice of her own conscience, or in the voice of the thunders, or in one or more of the multitudinous voices of Nature. It is enough for us to know that in some way or other man fell from the position of perfection in which a perfect creative being must have placed him. Of course, Moses might have written a few volumes on the interesting subject of creation, and a metaphysical disquisition on the subtleties of the human mind and its relation to the principles of good and evil; he might also have explained the ancient mythologies, geology and astronomy, and all the other mysteries and sciences, but for my part I think he showed excellent taste in writing just as he did. The story of creation, as found in Genesis, is a marvel of condensation which the human mind has never surpassed. And it does no violence to human reason to assume that the persons for whom Moses wrote understood it in a perfect sense.

[Written for the MEDICAL BRIEF.]

Virginia Examination Questions.

CHEMISTRY.

1. Define valence, base, a salt, dialysis, alloy.
2. Describe the chemistry of alcohols and ethers.
3. Give formula of ammonia. The sources and uses of ammonia in medicine and the arts.
4. Give chemistry of respiration, showing what is inhaled, what is exhaled, and how the gases enter and leave the blood.
5. Show by equation how nitric acid is formed by the action of sulphuric acid on potassium nitrate.
6. Complete the following equations:

$$AG\ No_3 + Na\ Cl =$$
$$_4H\ F + Si\ O_2 =$$

TOXICOLOGY.

1. Give symptoms and treatment for carbolic acid poisoning.
2. State symptoms of chronic arsenic poisoning with treatment for same.
3. Describe the difference between alcoholic, uremic and opium coma.

MEDICAL JURISPRUDENCE.

1. Define medical jurisprudence.
2. Give the reliable signs of death.
3. How would you distinguish between insanity and idiocy?

OBSTETRICS, GYNECOLOGY, AND PEDIATRICS.

Dr. H. M. Nash, Chairman; Drs. W. W. Wilkinson and W. B. Robinson, Examiners.

1. What signs are brought out by abdominal palpation in the last stages of pregnancy, and their relative value?
2. Detail briefly the hygienic measures necessary for the successful issue of a pregnancy.
3. Define pelvimetry; what measurements obtained thereby should determine interferences?
4. What circumstances, other than pelvic contractions, may cause dystocia?
5. Describe the management of delivery in breech presentations.
6. Describe briefly an operation for relaxed pelvic outlet.
7. Detail the symptoms and possible terminations of pelvic peritonitis.
8. Treatment of rectovaginal fistula.
9. What therapeutic agents should be cautiously exhibited in infancy, and mention some that they bear proportionately better than adults?
10. Mention the most important diseases of the larynx in children, giving the causes for their greater danger.

SURGERY.

Dr. Samuel Lile, Chairman; Drs. E. T. Brady and R. M. Slaughter.

1. Give the diagnosis and treatment of acute osteomyelitis.
2. Give the cause and treatment of varicose ulcers.
3. Name the surgical diseases common to man and the domestic animals.

4. Give the differential diagnosis between (a) concussion of the brain so-called, (b) fracture of the skull, and (c) rupture of the middle meningeal artery.

5. Give briefly Cohnheim's hypothesis as to the origin of tumors.

6. What is hydrocele? Give diagnosis and treatment.

7. Give the nature and treatment of Potts' fracture.

8. Name the dangers and give the treatment of carbuncle.

9. Give the causes and treatment of cystopetropyelitis.

10. Name the dislocations of the elbow. Give the symptoms and treatment of the backward dislocation.

ANATOMY AND EMBRYOLOGY.

Dr. C. W. Rodgers, Chairman; Drs. Robert Randolph and H. U. Stephenson, Examiners.

ANATOMY.

1. Describe the upper extremity of the tibia.

2. Describe the ligaments of the hip joint.

3. Describe the external oblique muscle, including a description of the superficial abdominal ring.

4. Give the commencement, termination, relations, and branches of the brachial artery.

5. Give the commencement, termination, and relations of the internal jugular vein.

6. Describe the duodenum.

7. Give origin, course, and distribution of the median nerve.

8. Name the muscles, nerves and arteries severed by a cross-section of the thigh at the junction of the middle with the lower third.

EMBRYOLOGY.

1. At what stage of embryonic life does the development of the alimentary canal commence, and from what layer of the blastoderm is it formed?

2. What changes occur in the vascular system of the fetus at birth?

MATERIA MEDICA—HOMEOPATHIC.

Dr. E. C. Williams, Hot Springs, Va., Examiner. (Answer four blocks of questions.)

1. (a) Give the physiological action of phosphorus. (b) Mention the tissues or organs especially acted on by (1) rheum, (2) phytolacca, (3) hammamelis, and 4() caulophyllum.

2. (a) Describe the urinary symptoms of (1) cantharis, (2) lycopodium, and (3) nux vomica. (b) Give the mental symptoms of (1) ignatia, (2) pulsatilla, and (3) platinum.

3. (a) Give five general characteristics of each of the following: (1) bryonia, (2) sulphur, (3) kalii bichromicum. (b) Give the physiological action of aconite.

4. (a) Give the laryngeal symptoms of (1) aconite, (2) spongia, and (3) hepar sulphur. (b) Differentiate the skin symptoms of (1) rhus toxicodendron, (2) graphites, and (3) sulphur.

5. (a) Give the abdominal symptoms of (1) belladonna, (2) pulsatilla, and (3) terebinthina. (b) Mention the tissues or organs affected by (1) trillium pendulum, (2) thuja, (3) petroleum, and (4) lilium tigrinum.

THERAPEUTICS—HOMEOPATHIC.

Dr. E. C. Williams, Hot Springs, Va., Examiner. (Answer four blocks of questions.)

1. (a) Give the indications for the use of antimonium tartaricum in bronchitis. (b) State the general measures applicable in a case of pneumonia. (c) Differentiate bryonia from nux vomica in a case of acute gastritis. (d) Mention the principal clinical uses of (1) trillium pendulum, and (2) rhododendron.

2. (a) Give the indications for the use of spigelia in neuralgia. (b) Differentiate calcarea carbonica from podophyllum in the diarrhea of children. (c) Mention three remedies of especial use after an excess of mercury. (d) Differentiate bryonia from lycopodium in a case of chronic constipation.

3. (a) Give the treatment for acute uremia. (b) Mention the principal clinical uses of thuja and dulcamara. (c) Give the symptoms for the use of aloes and æsculus in hemorrhoids. (d) Differentiate veratrum album from arsenicum in a case of cholera.

4. (a) Differentiate silica from calcarea carbonica in otorrhea. (b) Give the indications for the use of apis in scarlet fever. (c) Mention the principal clinical uses of (1) aurum, (2) platinum, and (3) veratum viride. (d) Give the indications for the use of gelsemium in epidemic influenza.

5. (a) State the principal clinical uses of sanguinaria and rhododendron. (b) Give the symptoms for the use of arsenicum album in acute catarrhal rhinitis. (c) Mention two remedies of especial use in mastitis and give indications for each. (d) Differentiate mercurius corrosivus from nux vomica in a case of dysentery.

PRACTICE, ETIOLOGY, AND DIAGNOSIS.

1. To what disorders are persons of a lithemic diathesis most prone? Outline dietary and treatment of the lithemic state.

2. State early symptoms and causes of tuberculosis.

3. State physical symptoms and diagnosis of asthma.

4. In what conditions is severe pain a prominent symptom; and to what extent does localized pain aid recognition?

5. State cause and management of acute milk infection.

6. Describe the stools of acute enteritis, typhoid, obstructive jaundice.

7. Differentiate between scabies and pustular eczema.

8. What is aphasia? Give cause and differentiate between the ataxic and aphasic forms.

9. Give symptoms and treatment of chorea.

10. What drugs influence character of stools?

11. What clinical significance attaches to cardiac arythmia?

12. Cause and treatment of stomatitis.

PATHOLOGY.

1. Name the phenomena comprised (changes which occur) in an inflammatory process.

2. State the systems through which, and how necrosis is produced by disordered nutrition.

3. What is leucopenia, and in what important disease does it occur?

4. What is an exudate, and what is the character of the exudate in lobar pneumonia, broncho-pneumonia, and acute peritonitis?

5. Name the histological elements to be found in the fibro-osteo-chondro-myxo-sarcoma. By what route do the metastases of sarcoma usually occur?

6. Give the morbid anatomy of acute articular rheumatism (rheumatic fever), and name the possible complications of this disease.

BACTERIOLOGY.

1. Define and illustrate the terms aerobic, obligate, plemorphous, and sporogenous, and name and explain the two varieties of chemotaxis.

2. Describe the micro-organism of anthrax, and give its pathogenicity.

3. What special culture medium is required for the growth of the gonococcus? Give the pathogenicity of the gonococcus.

NEUROLOGY.

1. Give the etiology of locomotor ataxia.

2. Give the symptoms of cerebral apoplexy, and name the conditions the coma of which may be simulated by an apoplectic stroke.

3. Give the prognosis in tubercular meningitis and in epidemic cerebro-spinal meningitis, and the general indications of treatment in the latter.

MATERIA MEDICA.

1. Name, with dose of each, the preparations of salicylic acid. Give its physiological action, and state in what form it is to be administered.

2. Give the preparations of belladonna. Describe the toxic effects and give antidotes.

3. Give the chief alkaloid of cinchona; its dose, and its physiological action.

4. Name the preparations of the chlorides of mercury. Give dose and differentiate the physiological action of each.

5. Name the mineral acids and mention the special properties of each.

6. Give the physiological action of opium. Name its most important alkaloids and give dose of each.

THERAPEUTICS.

1. Into what two classes are bitters divided? Give therapeutic uses. Contraindications. Time of administration.

2. How may the two chlorides of mercury be administered? Give their therapeutic uses. In bilious attacks when you give calomel, what remedy often used to allay nausea would you be particular not to give?

3. Why would you use a strong solution of arsenic when applied over large surfaces? In giving Fowler's solution in increasing doses, what untoward symptom would indicate that the dose should not be further increased?

4. (a) Give the therapeutic application of drugs in the different stages of pneumonia. (b) Give the comparative value of chloroform and ether as an anesthetic.

5. (a) Describe the therapeutic uses of iodin and its salts. (b) What are the therapeutic uses of diuretics?

6. Prescribe a local application for erysipelas, for rhus toxicodendron poisoning. Name some remedies used for epistaxis, croup, singultus, ptyalism. Write a prescription for night-sweats of phthisis, for ascites.

PHYSIOLOGY.

1. What are the uses of the blood, and what is the difference between arterial and venous blood?

2. What is the effect of the pneumogastric nerve upon the heart?

3. What is meant by the term vesicular murmur?

4. What are the characteristics of peptones?

5. Name the pancreatic ferments and describe the action of each.

HYGIENE.

1. Name the qualities desirable in water for drinking and domestic purposes.

2. Give the best methods for disinfecting a house in which there has been a case of smallpox.

3. What precautions should be taken by a physician attending a case of diphtheria?

HISTOLOGY.

1. What is meant by endochondral formation of bone? Describe process briefly.

2. Describe formation of an artery, giving cause.

LARYNGOLOGY, RHINOLOGY, OPHTHALMOLOGY AND OTOLOGY.

Dr. A. S. Priddy, Chairman; Drs. H. M. Nash and O. C. Williams, Examiners.

LARYNGOLOGY.

1. What are the symptoms, course, and treatment of acute laryngitis?

2. Give the diagnosis and treatment, both general and special, of laryngismus stridulus.

3. Give the symptoms, course, some common complications, and treatment of acute follicular tonsillitis.

RHINOLOGY.

1. What anatomical arrangements within the nares render the treatment of chronic rhinitis difficult?

2. Give the most generally accepted theory of predisposing and exciting causes of hay fever, and describe its symptoms.

OPHTHALMOLOGY.

1. What are the microscopical appearances of the most common forms of keratitis, and the appropriate treatment?

2. Give the causes, symptoms, and general local treatment of trachoma.

3. Give cause, symptoms, and treatment, both prophylactic and remedial, of ophthalmia neonatorum.

OTOLOGY.

1. Define tinnitus aurium and give the cause of it.

2. Give briefly the diagnosis and treatment of acute otitis media.

Book Notices.

The *American Medical Compend*, Toledo, Ohio, issues a "Byron Robinson Number" for January, 1907. From the long acquaintance of our readers with Dr. Robinson as a contributor to the BRIEF, we feel assured that they will be interested in seeing a copy of this special issue.

MEDICAL JURISPRUDENCE, FORENSIC MEDICINE AND TOXICOLOGY. By R. A. Witthaus, A. M., M. D., Professor of Chemistry, Physics and Toxicology in Cornell University; and Tracy C. Becker, A. B., LL. B., Counselor at Law, Professor of Criminal Law and Medical Jurisprudence in the University of Buffalo. With the collaboration of August Becker, Esq., Chas. A. Boston, Esq., Hon. Goodwin Brown, W. N. Bullard, M. D., G. C. Cameron, M. D., J. Clifton Edgar, M. D., Jas. Ewing, M. D., E. D. Fisher, M. D., J. C. Johnson, M. D., D. S. Lamb, M. D., H. P. Loomis, M. D., W. B. Outten, M. D., Roswell Park, M. D., J. Parmenter, M. D., Irving C. Rosse, M. D., E. V. Stoddard, M. D., George Woolsey, M. D., J. H. Woodward, M. D. Second edition, Vol. I. New York: William Wood & Co. Price, $6.00 per volume. Sold only by subscription in the full set of four volumes. Can also be had in law sheep at $7.00 per volume.

A great deal of comment has been made of recent times in regard to expert evidence. In the present work the needs of the legal profession are recognized as well as those of the medical. It has long been considered to be the province of the legal portion of a work on medical jurisprudence to set forth only those rules of law which relate to the criminal responsibility of the insane, and the status of medical men when called into court as expert witnesses. Meanwhile, statutes have been passed, and decisions of the courts rendered in all enlightened countries, which have gradually but firmly built up a broad system of law, which defines and governs the legal relation of the physician and surgeon to society. His right to practice his chosen profession has been limited and determined by statutory enactment. His responsibility for due care and skill in the treatment of his patients is considered. His competency as a witness in expert cases has been established by numerous decisions. His right to *just* compensation for services rendered, and medicines and appliances furnished, has been recognized and placed upon the same legal footing as rights arising under any other contracts, but there is no law which governs extortion in regard to services rendered. Will it not be of much advantage to both the medical and legal profession to have at hand a work containing the results of the latest decisions of the courts, and the latest statutory regulations concerning responsibilities. The conviction that both these professions require all of the information mentioned in this work has been the aim of the authors and collaborators. We think they have done their work cautiously and well.

PIONEERS OF PROGRESS. By T. A. Bland, M. D., Author of "Farming as a Profession," "Life of Benjamin F. Butler," "Esau," "How to Get Well and How to Keep Well," "In the World Celestial," etc. Chicago: T. A. Bland & Co. Price, $1.25.

Dr. Bland's work is essentially American, and reflects the various social relations growing out of the true spirit of Christian Democracy. The pages are full of life, action, conversation and character. Nowhere, we are persuaded, can there be found truer word pictures of character in the independent sphere of activity and usefulness. How often would interest waver did not some friend, who knew, depict the life and character of our pioneers. We are treated to so much of the high, strong and intense of the characteristics of men of today that such a work as this is really refreshing. Dr. Bland is himself a pioneer of progress in more ways than one, therefore we commend his work to the youth of today.

GOLDEN RULES OF SURGERY. Aphorisms, Observations and Reflections on the Science and Art of Surgery. Being a guide for surgeons and those who would become surgeons. By Augustus Charles Bernays, A. M., M. D. (Heidelberg), M. R. C. S. (Eng.), Life Member of the German Society for Surgery of Berlin, Chief Surgeon Lutheran Hospital, and for twenty years Professor of Anatomy and Surgery in St. Louis, Mo., U. S. A.; Member Association for the Advancement of Sciences, of the St. Louis Academy of Sciences, etc. St. Louis: The C. V. Mosby Medical Book Co. Price, $2.50.

In years past the author of this work thoroughly elaborated his writings in THE

MEDICAL BRIEF by some of the most intricate surgical operations. We wish to call attention to one of the first important operations by Dr. Bernays, contributed to THE MEDICAL BRIEF January, 1887, as follows: "Gastrotomy for the Removal of a Swallowed Knife. Recovery of the Patient." (fully illustrated). In nineteen days the patient was following his daily avocations as though nothing had happened. We call attention to this to show that the author is worthy of consideration.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially-Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene, and other Topics of Interest to Students and Practitioners, by Leading Members of the Medical Profession Throughout the World. Edited by A. O. J. Kelly, A. M., M. D., Philadelphia. With the collaboration of William Osler, M. D., John H. Musser, M. D., James Stewart, M. D., John B. Murphy, M. D., A. MacPhedran, M. D., Thos. M. Rotch, M. D., John G. Clark, M. D., J. W. Ballantyne, M. D., James J. Walsh, M. D., John Harold, M. D., Edmund Landolt, M. D., Richard Kretz, M. D., etc. Illustrated in colors and black and white. Philadelphia: J. B. Lippincott Co. Price, cloth, $2.00; half leather, $2.25.

Volume II, Sixteenth Series, 1906, is now at hand, and the features that have made it a success in the past are fully apparent. Through all these series the publishers have so well succeeded in the value of the contents of these clinics that today it can be found in all well-appointed libraries, and its pages will show the interest taken in it by the well-thumbed pages. If you do not take these clinics it is worth your time to investigate it.

TOXICOLOGY, The Nature, Effects and Detection of Poisons, with the Diagnosis and Treatment of Poisoning. By Cassius M. Riley, M. D., Professor of Chemistry and Toxicology in Barnes University, and Dean of Barnes College of Pharmacy; Member of American Medical Association; Member of American Pharmaceutical Association. Third edition, revised and enlarged, with illustrations. Philadelphia: P. Blakiston's Son & Co. Price, $1.50.

Any physician or chemist who is personally acquainted with Dr. Riley would expect just such a practical work from his pen. The student will find such practical and useful matter that larger textbooks would rarely be necessary. The busy physician will find it a ready reference book on the diagnosis and treatment of poisoning, and plain statements in connection with the individual poisons and the latest treatments, also the simplest and most easily applied tests for their recognition. This is a practical work by a practical author—theories find no place on its pages.

A MANUAL OF OTOLOGY. By Gorham Bacon, A. B., M. D., Professor of Otology in the College of Physicians and Surgeons, Columbia University, New York; Aural Surgeon, New York Eye and Ear Infirmary. With an introductory chapter by Clarence John Blake, M. D., Professor of Otology in Harvard University. Fourth edition, revised and enlarged. Handsome 12mo. volume of four hundred and eighty-five pages, with one hundred and thirty-four illustrations and eleven plates. New York and Philadelphia: Lea Brothers & Co., publishers. Price, cloth, $2.25.

The rapid sale of three revisions of this work shows the appreciation in which it is held by the profession. The new edition is greatly improved, new illustrations have been added, and a number of new pages were found necessary owing to important advances. Among the new topics considered will be found Osteomyelitis, Primary Jugular Bulb Thrombosis, and Suppurative Inflammation of the Labyrinth. These, with the re-written chapters on other important matters, make this up-to-date volume valuable, especially in a clinical sense. Have you secured a copy?

THE PRACTITIONERS' VISITING LIST FOR 1907. An invaluable pocket-sized book containing memoranda and data important for every physician, and ruled blanks for recording every detail of practice. The Weekly, Monthly and Thirty-Patient Perpetual contain Thirty-two pages of data and one hundred and sixty pages of classified blanks. The Sixty-Patient Perpetual consists of two hundred and fifty-six pages of blanks alone. Each in one wallet-shaped book, bound in flexible leather, with flap and pocket, pencil and rubber, and calendar for two years. Price by mail, postpaid, to any address, $1.25. Thumb-letter index, twenty-five cents extra. Descriptive circular showing the several styles sent on request. Philadelphia and New York: Lea Brothers & Co., Publishers.

CHEMISTRY: GENERAL, MEDICAL AND PHARMACEUTICAL, INCLUDING THE CHEMISTRY OF THE U. S. PHARMACOPOEIA. A Manual of the Science of Chemistry and its Applications to Medicine and Pharmacy. By John Attfield, F. R. S., M. A., Ph.D., F. C. S., etc., Professor of Practical Chemistry to the Pharmaceutical Society of Great Britain, etc. New (nineteenth) edition, specially revised by the author to accord with the New U. S. Pharmacopœia, edited by Leonard Dobbin, Ph.D., F. I. C., etc., Lecturer on Chemistry in the University of Edinburgh, etc. 12mo., seven hundred and sixty pages, illustrated. Philadelphia and New York: Lea Brothers & Co. Price, cloth, $2.50.

The revision of Attfield's Chemistry was confided by the author to Mr. Leonard Dobbin, of the University of Edinburgh and Examiner in Chemistry on the Board of Examiners for Scotland of the Pharmaceutical Society of Great Britain. The work has been brought thoroughly up-to-date and to accord with the most recent Pharmacopœias of the United States and of Great Britain. The original plan of the book has been strictly adhered to, as seventeen large editions in the United States and eighteen in Great Britain are an evidence of the approval of the professions of medicine and pharmacy in the two great English-speaking nations of the world.

STOHR'S HISTOLOGY. Arranged Upon an Embryological Basis. By Dr. Frederic T. Lewis, Assistant Professor of Embryology at the Harvard Medical School. From the twelfth German edition. By Dr. Philipp Stöhr, Professor of Anatomy at the University of Würzburg. Sixth American edition, with four hundred and fifty illustrations. Philadelphia: P. Blakiston's Son & Co. Price, $3.00.

Some simplicity has been made in regard to the names that have previously been used; for instance, the following: Instead of saying Lieberkühn's Glands, use Intestinal Glands, and for Brunner's Glands, use Duodenal Glands; for Stenson's Duct, use Carotid Duct; and all similar changes have had recognition to aid the student in memorizing names in accordance with modern views. And in regard to synonyms, this work has suggested the rejection of over five thousand, as soon as possible, and the author has placed on record the rejected names. It may be difficult for the older anatomists to immediately conform to the new nomenclature, yet the author deems it a duty to state the facts. Excellent as the German nomenclature is, as a whole, it is not beyond improvement, and it may be desirable for a committee of the Association of American Anatomists to publish in their English forms a corresponding list of names. The writer has been informed that Messrs. Blakiston's Son & Co. have in press such a list prepared by Prof. Barker, and entitled "Anatomical Terminology." The orderly arrangement of these descriptive names makes the Latin list—and undoubtedly their English version also—an excellent means by which students may review anatomy.

GOLDEN RULES OF PEDIATRICS. Aphorisms, Observations and Precepts on the Science and Art of Pediatrics, Giving Practical Rules for Diagnosis and Prognosis, the Essentials of Infant Feeding and the Principles of Scientific Treatment. By John Zahorsky, A. B., M. D., Clinical Professor of Pediatrics, Washington University, Medical Department, St. Louis; Ex-President of the Bethesda Pediatric Society; Attending Physician to the Bethesda Foundlings' Home; Member of the American Medical Association and of the St. Louis Academy of Science, etc. With an Introduction by E. W. Saunders, M. D., Professor of Diseases of Children and Clinical Midwifery, Washington University, etc. St. Louis: The C. V. Mosby Medical Book Co. Price, $3.00.

Why waste your time in reading long, drawn-out articles on a subject, when short, pithy paragraphs give you the best information? We have before us a work that gives the cream of the subject in short, terse expressions. The author says: "Some favorite ideas are controverted by good authority, but, nevertheless, a book of aphorisms, having personal views back of it, is probably more interesting, if not more valuable, than a compend of undisputed maxims."

ABDOMINAL OPERATIONS. By B. G. A. Moynihan, M. S. (London), F. R. C. S., Leeds. Senior Assistant Surgeon at Leeds General Infirmary, England. Second revised edition, greatly enlarged, with three hundred and five original illustrations. Philadelphia and London: W. B. Saunders Co. Price, cloth, $7.00; half morocco, $8.00.

Only a few months have intervened since the publication of the first edition of this work, and the ready exhaustion of this edition encouraged the author to

give a larger and more complete revised edition. A work of this kind was certainly needed, especially by the progressive surgeon. There are three surgeons who deserve especial mention as contributing to the pages of this book, viz., Dr. W. J. Mayo, Dr. J. B. Murphy and Dr. Mayo Robson. There are manifold advantages thus to be gained in valued thought and scientific attainments. This work will open your eyes along this line of practice.

A TREATISE ON DISEASES OF THE SKIN. For the use of Advanced Students and Practitioners. By Henry W. Stelwagon, M. D., Ph. D., Professor of Dermatology Jefferson Medical College, Philadelphia, and Clinical Professor of Dermatology Woman's Medical College, Philadelphia. Fourth edition, revised. Philadelphia and London: W. B. Saunders Company. Price, cloth, $6.00; sheep or half morocco, $7.00.

This volume contains one thousand, one hundred and thirty-six pages, with two hundred and fifty-eight text-illustrations and thirty-two full-page lithographic and half-tone plates. About eighteen pages have been added to this revision, yet the work has not been increased in size, owing to the elimination of some matter that was considered not necessary. To further enhance the value of symptomatology and diagnosis—important matters in skin diseases—some new cuts have been added, and since these have been of the more common diseases it lends additional value to the general practitioner, owing to the fact that he treats those diseases of the skin not too complicated, and belonging to the specialist.

A HISTORY OF CHEMISTRY, from Earliest Times to the Present Day. Being also an Introduction to the Study of the Science. By Ernst von Meyer, Ph. D., Professor of Chemistry in the Technical High School, Dresden. Translated with the author's sanction by George McGowan, Ph. D. Third English edition. Translated from the third German edition, with various additions and alterations. New York and London: The Macmillan Company. Price, $4.25.

The history of chemistry proper begins with Robert Boyle, who taught, as its main object, the acquisition of a knowledge of the composition of bodies. The conception of this aim marks the date from which chemistry may be regarded as a science. This merit belongs to an Anglo-Saxon (Boyle). Next comes a Frenchman, named Lavoisier, who gives the stepping stone of advance. Then down through the ages comes Paracelsus, Van Helmont, de la Böe Sylvius, Tachenius, and others of note, came the period of medical or iatro-chemistry, and then from the middle of the seventeenth century iatro-chemistry gave way to other branches. Physical chemistry, with the accompanying doctrine of affinity, has made immense strides, and has greatly broadened its foundations during the last two decades. And the key that opened the whole advance is combined in the elegant pharmaceuticals of today. In going back to the history of the Egyptians, Phœnicians, Jews, and, in fact, other ancient times, we find that these peoples have lain the foundation for the primary knowledge that was used as a basis for future developments.

PREVALENT DISEASES OF THE EYE. A Reference Handbook, Especially Adapted to the Needs of the General Practitioner and the Medical Student. By Samuel Theobald, M. D., Clinical Professor of Ophthalmology and Otology in the Johns Hopkins University; Ophthalmic and Aural Surgeon to the Johns Hopkins Hospital and to the Baltimore Eye, Ear and Throat Charity Hospital; Consulting Ophthalmic and Aural Surgeon to the Home for Incurables and to the South Baltimore Eye, Ear and Throat Charity Hospital. With two hundred and nineteen illustrations and ten colored plates. Philadelphia and London: W. B. Saunders Co. Price, cloth, $4.50; half morocco, $5.50.

The majority of the works published on diseases of the eye are not practical for use by the general practitioner; therefore, when a work that is written along the plain lines of diction such as this one, it appeals to the general practitioner, owing to the fact that he is not a specialist and therefore needs something for his special guidance. When a general practitioner can diagnosticate properly, his knowledge of *materia medica* comes to his aid and half the battle is won. It is well for the family physician to book himself upon all classes of cases, and when beyond his knowledge to call in the specialist and then lend his aid to retain his trade on the family ailments. Every practitioner should add a work such as this to his library for reference.

Editorial.

Talks Plainly.

The editor of the *Medical Fortnightly* talks plainly in the following:

We know that the pharmacist may be profited to a greater degree if the Formulary products should in a measure supplant the proprietaries, but until he mends his ways we have little reason for concern about his interest in the matter; the little corner drug-store, whose name is legion in this city, will prescribe for more patients in an evening than will any physician in the neighborhood in a day; we have all at one time or another suffered from substitution to an extent that makes us somewhat incredulous whether the druggist is in his turn mindful of our material or scientific success—without the druggist the miserable trade in harmful patent medicines which are absolutely secret could not exist. Taken all in all we can not see that we have any call to worry about the profits of the druggists under existing conditions.

The proprietary which has not the merit to stand on will never long continue, and a fight on proprietaries, simply because they belong to that class of remedies, will be unavailing. Nor will the fact that the manufacturer and the dispenser disagree as to who should get the greater profit from the preparation and sale of a product mean much to our profession. Then, again, many of our best and most reliable proprietaries can not be duplicated in the drug store, for the reason that the scientific process of manufacture requires days, weeks, or sometimes months.

Not Caused By a Microbe.

A correspondent asks if, in our opinion, consumption is caused by a microbe, and is tuberculin a cure for it. In reply, I will say, in the opinion of the Editor, consumption is not caused by a microbe, but is a house disease. It is a fact that nearly all menagerie animals die of consumption, and no wild animal not confined ever dies of consumption. In regard to tuberculin, it is a fake and never was

of any value in consumption, and is played out, as the Editor predicted. It is one of the foreign fads that was taken up by so-called scientific men.

Makes Them Profane.

Good roads are a great comfort to doctors.

Ground oyster shells are a good thing to fill holes in the road with.

Communities that have barbarian authorities use whole or unground oyster shells.

This cuts the doctor's tires on his buggy and makes him use cuss words.

So Disinterested.

The schemers who are getting up the very poor imitations of standard proprietary remedies in use by the profession aim to eventually publish a book under the head of Pharmacopœia remedies, which every physician and druggist is supposed to buy.

May we ask who will share the profits of this book?

Queer.

We heard a doctor say he practiced medicine exclusively for the benefit of humanity.

An acquaintance, who overheard the remark, replied to us, "It's queer that this doctor has the reputation of being the best collector in the city."

Standard Remedies the Best.

Don't you think, as a rule, a remedy made by a careful manufacturer, who has his reputation at stake, is liable to be better than a product made by guesswork by every Tom, Dick or Harry?

A Necessity.

People would be surprised to know the large amount of sickness and death caused by bad plumbing. Probably more than any other cause. There is a necessity for schools for plumbing just like there are schools for medicine and dentistry. A plumber should have a diploma just like a doctor and dentist.

The Boards of Health should inspect the hotels, school houses, court houses, and other public buildings. A knowledge of good plumbing should be a part of a doctor's education.

Trifolium Pratense.

BY J. A. BURNETT, M. D.,
Dean Spring, Ark.

A well-known writer, in speaking of trifolium pratense, which is also known as red clover, said it was deobstructant and sedative, and that the blossoms had long been used in the form of infusion in whooping cough, which they are said to relieve promptly. He considered it a success in the treatment of scrofula, and of value when used as a wash in ill-conditioned ulcers. His dose of the fluid extract was one-half to one drachm, and five to twenty-five grains of the solid extract. The solid extract is applied to cancers, and is thought by some to be a remedy for cancer.

Trifolium is considered to be a good alterative. It is also antiseptic, antispasmodic and deobstructant, and of value in scrofula, syphilis, and various skin diseases. It is of value in spasmodic cough, besides whooping cough, and useful in cough of rubeola, bronchitis, laryngitis, and irritable states of the larynx.

Some authors recommend it for pulmonary troubles in general.

Dr. Cook recommends the following:

Trifolium and ampelopsis, each four parts; stillingia, corydalis, and berberis aquifolium, each two parts, and xanthoxylum bark, one part. He said: "I have used this formula liberally in my own practice, and am justified in urging it upon the attention of the profession for degenerate ulcers, scrofula, and secondary syphilis—having known it to soften and remove gummata without any use of the weakening potassium iodide. I name it 'Trifolium and Berberis Compound.'"

The old alterative vegetable remedies deserve more study, and trifolium will be found to be among the most important of this class of remedies.

[Written for the MEDICAL BRIEF.]

Rheumatoid Arthritis.

BY WILLIAM MURRELL, M. D., F. R. C. P.,

Physician to the Westminster Hospital and Examiner in the University of Aberdeen.
London, England.

The names rheumatoid arthritis, rheumatic gout, osteo-arthritis, and arthritis deformans are applied to a group of diseases which includes many subvarities, and was formerly believed to be allied to gout and rheumatism, although it has little affinity with either. It is a polyarticular disease, due, probably, to a specific organism. It was at one time regarded as essentially a chronic affection, but is now known to occur as an acute disease. Included under these names are a variety of affections having certain points of resemblance, but not, of necessity, identical, so that a revision of nomenclature has become essential. In this category we now place:

1. The chronic arthritis of middle-aged women.
2. Acute rheumatoid arthritis.
3. Chronic arthritis, with acute exacerbations.
4. Senile osteo-arthritis.
5. Various forms of the disease in children.

The term rheumatoid arthritis is, for convenience, retained as the generic name of the group, but it is open to objection, and probably when our knowledge of the subject is more accurately defined, will cease to be used. It will facilitate matters if the ordinary and more common form is first described.

Chronic Rheumatoid Arthritis.—This occurs most frequently in young and middle-aged women, but is met with in both sexes. Childhood and youth are, to a great extent, exempt; it begins to be common about the age of thirty, and is especially frequent in women at the climacteric period. It is commoner in the poorer classes, but the well-to-do are by no means free. It is often ascribed to exposure to cold and damp, but all debilitating influences, such as defective hygienic conditions, mental anxiety, repeated pregnancies, protracted lactation act as predisposing causes. It sometimes follows in the wake of influenza or endocervicitis and endometritis, or it may be associated with Riggs' disease, and other sore and suppurating conditions of the mouth and gums.

The joints most frequently attacked are those used in sewing, knitting, and other occupations in which women indulge. Its onset is gradual, and there may be a history of general ill-health and bodily depression, possibly with menstrual disturbance. There may be some elevation of temperature, but, at all events, after a short period of malaise and discomfort, there is swelling and tenderness of one or

more of the small joints of the hand. The joints most frequently affected at the onset are the metacarpo-phalangeal, but the knees are involved early. The inflammation subsides with rest and treatment, but after a few weeks it returns, and other joints are affected. The mobility of the joints is impaired, the stiffness being most marked in the early morning, or after a long rest. With rubbing and exercise, the articulations are, at first, rendered more supple, but after a time the movements are materially decreased. There is not much pain, and there is very little tenderness. The articular ends of the bones become thickened and increase in size. Any attempt at movement is attended with grating or crepitus in the joint, which is felt by the patient, or on manipulation. Little by little the disease travels all over the body, until every joint is implicated. The shape and appearance of the joints become altered, partly by the presence of osteophytes and partly by the thickening of the capsular ligaments. The muscles around the joint, and even of the entire limb, undergo a process of atrophy, the wasting being marked. There may be a spurious ankylosis, due not so much to the changes in the articular surfaces, as to contraction of the ligaments and tendons. The condition of the hands is characteristic; they are thin from the absorption of fat and other soft tissues, and the ends of the bones stand out prominently. The fingers are turned outwards, and there is much distortion. All the fingers, with possibly the exception of the little finger, are flexed; the metacarpal ends of the first phalanges are dislocated towards the ulnar side, less commonly towards the radial. As a result of these changes the digits are arranged in an imbricate fashion, one over the other, until the hand assumes the appearance of a bird's claw. The thumb is usually spared, and by its aid the patient succeeds in performing many useful movements after the rest of the hand is rendered useless. Numbness of the skin, tingling, pigmentation, and a peculiar glassy or shiny appearance are common. The disease is slow in its progress, and is made up of a series of acute attacks or exacerbations, each accompanied by fever and followed by increased deformity, until the patient is reduced to the condition of a helpless cripple. After months or years of suffering the acute symptoms may, without any apparent cause, subside leaving the patient with several joints stiff and hopelessly damaged. There is no tendency to cardiac complication, and there is no deposit of urate of sodium in the joints. In many cases the nervous symptoms predominate, and it is not uncommon to find muscular cutaneous and vascular trophoneuroses, with neuritis and exaggerated reflexes. Some writers have been so impressed by the frequency of the occurrence of these phenomena that they have regarded the disease as one of purely nervous origin. Although this is the form of the disease ordinarily met with, there are certain cases which are difficult to distinguish from chronic gout; borderland cases, in which both diseases seem to be present.

Acute Rheumatoid Arthritis.—This is much less common than the chronic form or, possibly, it may be overlooked and confounded with rheumatic fever. It occurs more frequently in girls than in boys and usually commences in the fingers. There is a sudden onset and many joints, including the tempero-maxillary, may be attacked simultaneously. In addition to the joint affection, there are constitutional disturbances, such as elevation of temperature, rapid pulse, loss of appetite, headache, thirst, and constipation. It often runs a very acute course, and may completely cripple the patient in the course of a few weeks. The characteristic symptoms of acute rheumatism are absent, there is no sweating, and no tendency to pericarditis or endocarditis. Some anemia is always observed, but it rarely reaches a high degree of intensity, and but little importance can be attached to it, from the point of view of diagnosis. In the case of a girl, aged twenty-three, who has been for many years under my care, the disease advances by periodical acute exacerbations. The disease is chronic in its effects, but periodically there is a recrudescence of inflammation. These acute attacks occur every three weeks or a month, and precede the menstrual period. Sometimes they are accompanied by tonsillitis. Each attack is accompanied by

greater deformity of the smaller joints, both of the hands and feet.

By some it is maintained that there is no essential clinical or pathological difference between the chronic and the acute forms of the disease. It is urged that the variation in the symptoms of the two forms is simply an indication that the effects of an acute infection are chiefly local synovial inflammation, with rise of temperature; whilst in the chronic case the effects of the virus are more pronounced in the ends of the bones, the cartilages, and the nervous system. There is no sharp line of demarcation between the acute and the chronic forms.

Senile Osteo-Arthritis is a form of the disease met with in elderly people. It attacks the hip, the knee, and shoulder, and may involve the vertebra, giving rise to that condition known as "poker back," or *spondylitis deformans*. It is more common in the cervical than in the dorsal and lumbar regions. In the cervical form the vertebra may be completely locked together by osseous bridges, so that all movement is prevented, and the patient is unable to bend or rotate the head. Sometimes the head is bent forward, so that the chin almost touches the sternum. When the disease attacks the dorsal and lumbar regions, the spine is bent, the body is shortened and twisted, and there may be compression or irritation of the cord, of the nerves given off from it, and of the spinal ganglia. It is in these cases that we meet with shooting pains in the limbs, partial paralysis, and various trophic changes.

There are two varieties, one in which the disease is hereditary, or follows in the wake of an injury, and another in which these predisposing causes are absent. In the former, pain, anesthesia, and muscular atrophy are common, whilst in the latter they are rarely seen. In many cases the onset is distinctly traumatic, a blow or strain producing a slight arthritis, or a definite lesion, such as a detachment of the cartilage, or a dislocation or a fracture into the joint. The inflammation fails to subside, and goes on to the production of deformity. An additional strain is thrown on the other joints and they, in turn, are similarly affected. Sometimes the cause is mechanical, as when the spine is bowed by carrying heavy weights, or when the hands of a boatman permanently assume the position of holding an oar, or of a coachman in holding the whip or reins. In women, the right hand is affected from holding the needle, and the left from the position in which she holds the sewing. The disease is, usually, centripetal in its progress, spreading from the hand or foot to the trunk, but the hip is often involved before the knee.

With regard to pathology, the disease may be described as a degenerative process, consisting of a fibrillation breaking up and wearing away of the cartilages of the joints, accompanied by hypertrophy of the synovial folds at the edges. There is little or no inflammatory change, and it is essentially chronic in character. The hip is often first affected, and there is no accompanying anemia. This affection is sometimes met with in middle age, so that the term "senile," as applied to it is not distinctive. It may supervene on attacks of acute rheumatism, in fact, any diseased joint is liable to become the seat of osteo-arthritis.

In connection with the subject, reference must be made to the so-called *Heberden's Nodes*, which are common in rheumatoid arthritis, and have even been regarded as a special variety of it. These digitorum nodi consist of nodules varying in size from a pea to a bean, situated on the sides of the distal phalanges. They are more common in women than in men. In conjunction with their appearance, the smaller joints become swollen, tender and inflamed, but the larger joints escape. In some cases there is a gouty history, but in others it is absent. The condition is persistent and incurable. They consist chiefly of fibrous tissue and fibrin. In sections of the nodules bacteria have been seen, but their identity has not been determined. The nodules have been regarded as an indication of longevity, but, on the other hand, they are said to be the precursor of cancer. They are closely allied to the rheumatic nodules which occur in children after rheumatic fever.

In children there are two varieties included under the general term rheumatoid arthritis. These are:

1. A form of chronic joint disease described by Still, which is included provisionally.

2. An affection identical with the rheumatoid affection of middle-aged women, which sometimes follows an attack of acute rheumatism.

The form described by Still is a progressive enlargement of the joints, associated with general enlargement of the glands and of the spleen. Girls are more commonly affected than boys, and the majority of cases occur in children under the age of six. The onset is insidious. The child complains of stiffness of one or more joints, which slowly become enlarged, and, subsequently, other joints are affected. Sometimes the onset is acute, with rigors, and elevation of temperature. There is thickening of the tissues around the joints, and there is an absence of osteophytic growth. Creaking is noticed, but there is no actual bony grating. There is little pain and there is no redness or tenderness of the joints. Limitation of movement is always present, and the child is confined to bed. The joints most frequently affected are the knees, wrists, and those of the cervical spine. The ankles, and elbows follow next, but there is rarely any deformity of the hands. The affection is symmetrical, and there is no tendency to suppuration, or to bony ankylosis. The muscles show early indication of wasting. The most distinctive feature is the implication of the lymphatic glands. The enlargement is general, but involves chiefly those related to the affected joints; the glands most frequently enlarged are the supra-trochlear, those along the course of the brachial artery, those in Scarpa's triangle, in the iliac fossa, and in the posterior angle of the neck. Enlargement of the spleen is another characteristic symptom. The heart shows no evidence of valvular mischief, but there is some anemia. There may be pyrexia, and sweating is often profuse. There is an arrest of bodily development, and a child of twelve years of age may be mistaken for one of six. Respecting the etiology of the disease little is known. It may be microbic in origin, but of this there is no proof. It differs from the rheumatoid arthritis of adults in the absence of cartilaginous changes in the joints, in the order in which they are affected, and in the enlargement of the glands and spleen. It is probable that this is not a rheumatoid arthritis, but an infective process characterized by well-marked circum-articular manifestations, but with little implication of either the joints or their cartilages. This form of the disease is uncommon and must be regarded as a clinical curiosity. From careful inquiry I find that many men connected with special hospitals for children in London have never met with such cases. It is possible that they have overlooked them, or have failed to diagnose them; at all events, they are not common.

The second form met with in children is identical with the rheumatoid arthritis of adults, in its typical variety. It presents the same general enlargement of joints, with subsequent bony thickening. There is no enlargement of the glands and none of the spleen.

As to the causation of rheumatoid arthritis, there are good grounds for thinking that the disease is an infection, and that it is due to a diplococcus; an organism of this description was found in the joints of a man who suffered from the disease and died suddenly from another cause. This diplococcus, when cultivated and injected intravenously into rabbits, produced arthritic changes, and was again isolated from the joint exudations. It is not clear that the joint changes observed in these animals were identical with those of man. Von Dengun and Schneider obtained diplococci from the exudate in the joints of a patient who, at the time of his death, was suffering from arthritis deformans, and these organisms grew in all media, although they developed slowly. The injection of these cultures into the knee joints of rabbits gave rise to arthritic changes similar to those of rheumatoid arthritis. Although the exact nature of the organism responsible for the disease is still in doubt, it is microbic in origin. It affects one or two joints and spreads from them, not only to other joints, but to the adjacent structures, such as the muscles and nerves. Moreover, it frequently follows tonsillitis, influenza, enteric, and other infectious diseases. Whilst fully recognizing the fact that rheumatoid arthritis is due to a specific

organism, the influence of certain predisposing causes, such as cold, damp, sunless rooms, and other similar influences, can not be ignored. They lower vitality and induce conditions favorable to the introduction and development of various organisms. Sex and heredity are not without their influence.

The prognosis, in most forms of rheumatoid arthritis, is unfavorable with regard to the prospects of cure. When once developed its duration is, as a rule, limited only by the life of the patient. Usually the termination is by some intercurrent malady, which has but little relationship to the original disease. The senile form is most rebellious of treatment. Sometimes, although not commonly, there is an arrest of the progress of the disease, and when it seems to have done its worst and to have hopelessly crippled the patient, it comes to an abrupt end.

With regard to treatment, there is little to be said, and yet there are many suggestions which might be offered. Of internal remedies, the iodides—quite apart from the possibility of any syphilitic taint—are the most useful, but to be efficacious they must be administered in large doses. Arsenic is another remedy of repute, but its action is slow, and its administration must be continued for weeks, or even months. As a local application, the persistent application of a strong solution of iodine will be found useful. Amongst external remedies, warm baths and hot and cold salt douches may afford some amelioration. It is important to maintain the mobility of the joints, and for this purpose massage and electricity, in its various forms, may be resorted to. Treatment by mechanical or electrical vibration has, in some instances, been followed by improvement. For the relief of pain hypodermic injections of stovaine may be recommended. A residence during the winter in a hot, dry, bracing climate is often followed by an arrest of the disease. Harrogate, Bath and Buxton, in England, and Spa and Aix-les-Bains, on the continent of Europe, are resorted to during the summer months, but in winter Hammam R'Irha is the only health resort readily available, and even that for only a limited period.

Recently, at the Westminster Hospital, I have used a serum in these cases, and it has acted admirably. Provisionally, it may be called the "RA" serum. It is prepared according to the principles of ordinary serums, details of which are given in my article on "Serum Therapy" in the *Enclycopedia Medica*, Vol. 12, 1902. The following case illustrates this mode of treatment:

The patient was a single woman, aged thirty. Her illness commenced at the age of eighteen, with severe pain in the left great toe, the joint of which was swollen, red and tender. This lasted some weeks, but as it got better the left ankle, both knees, the right ankle and great toe, and the finger joints of both hands became, in turn, affected. Two years later she had a similar attack, lasting two or three months. Since then she has never been free from pain and swelling of the joints for more than a month at a time. She has had pains in the joints of the hands and feet, in the ankles, knees, wrists, elbows, shoulders, and more recently, in the jaw. Each attack has left her more crippled. Frequently, the attacks coincide with the menstrual periods, and often she has a sore throat with them. She has been many times in the hospital, has had much treatment, and has been frequently to Buxton, Bath, and Harrogate. The following is a note of her condition in January, 1906: Much deformity of both hands, hyperextension of the interphalangeal joints, partial flexion at metacarpophalangeal, more or less limitation of movements of all, and lateral displacement of some. Thickening, irregular in character, at bone ends. At both wrists ulnar deviation, with some limitation of movement. Much wasting of the small muscles of the hands. Walks without straightening the knees, and with some rigidity of the lower lumbar vertebra; the huddled position is more marked on the left side than on the right. The legs are held in a position of about one-fourth flexion on thighs, greater extension being, seemingly, limited by tendon shortening, flexion unlimited, movement of left ankle abnormally restricted. Some lipping of bone ends, and much deformity of toe joints. Marked limitation of power of opening mouth, with pain on making at-

tempt, so that there is difficulty in mastication. There is creaking in this, as in other joints. A few days later the temperature rose to 102° F., there was a sharp attack of tonsillitis, with inflammation of several of the small joints of both hands, of the left great toe joint, and of the knee, all of which, moreover, were swollen, red and tender. There was fluid in the left knee joint. These acute attacks occurred from time to time.

In addition to the ordinary medical treatment, hot air and Faradic baths, massage and Faradic current to the temperomaxillary joints, were tried but without benefit. On March 15, 1906, and again on the 17th, she had a hypodermic injection of five c.c. of the serum into the abdominal wall; there was no reaction. On the 22d she was given ten c.c., with the usual antiseptic precautions. Three hours later she had a rigor, and the temperature rose from normal to 103.2° F. She complained of feeling ill, pulse rapid, anorexia, nausea, vomiting three times, tongue moist, indented, and covered with white fur. There was diffuse erythema of the abdominal wall for an area of about four inches around the site of injection, and the inguinal glands were slightly enlarged. This condition lasted until the 26th, and gradually subsided. On April 3d, she was given another injection of ten c.c., followed by the same symptoms, which lasted two days. On the 14th, and again on the 24th, she had injections of five c.c., each of which was followed by a similar, but less severe disturbance. On the 16th, the following note was made: "Since the 23d there has been no joint pain. There is now no limitation of jaw movements, and the movements of fingers are freer. The patient stands straighter and walks with less deformity, and greater ease and comfort." No more injections were given, and on May 25 she was discharged, the following note being made: "There has been no return of pain in any joint. Patient now stands almost perfectly straight, and walks with but little restriction, except as regards rate. The knee extension is but little restricted. She has been free from any joint pain for two months. She can not remember having gone so long a time during the last ten years without an attack of acute pain of at least a few days' duration in one or more joints. After the patient's return home I hear from her constantly. In June she wrote "The new treatment has proved more ben eficial to me than anything I have eve had. For three months I have had n pain, and before that I suffered almos continuous pain for four years. I a sixteen pounds heavier than when I cam to London." In September she reporte that she was still further improving, an that her hands were so much better tha she could drive a pony-cart. Soon afte this there was a relapse, and in Decembe she was readmitted to the hospital. Sh was given, subcutaneously, five c.c. o the same serum, followed by a diffuse ery thema and a temperature of 100.5° F which persisted, with but little variation for twenty-four hours. Five days late another injection of five c.c. was given but the reaction was less marked. Afte another five days an injection of six c.c was given, but produced very little con stitutional effect. Three days later th same dose gave rise to a very marke reaction. The injections were continue throughout December, and to the earl part of January, 1907, and the beneficia effects on the joint condition were mos marked, the patient obtaining distinct re lief from her sufferings.

Other similar cases have been under my care, and I have no doubt that this line of treatment affords the only practicable method of cure.

[Written for the MEDICAL BRIEF.]

Syphilitic Disease of the Nervous System.

BY GEORGE OGILVIE, B. SC., M. D. (EDIN.), M. R. C. P. (LOND.),
Chevalier de la Legion d'Honneur,
Senior Physician to the French Hospital, London
and Senior Physician to the Hospital for
Epilepsy and Paralysis, London.
London, England.

No. II.

The discovery of the specific organism which has so long been present to the mind's eye of the pathologist, will do much to advance our knowledge of the syphilitic process, and settle much which now remains doubtful. No over-sanguine hopes for the clinical differential diag

nosis must be attached to its discovery. We know that the question, What is tuberculosis? has by no means been fully settled by Koch's discovery. The presence of the bacillus is not proof of tuberculous disease, while its absence is not proof against the tuberculous origin of the anatomical lesion. Moreover, the *intra vitam* diagnosis of syphilis of the nervous system is not likely to gain materially by the detection of the parasite, and it is the clinical aspect of the question which alone is considered on this occasion.

The diagnosis of syphilitic disease of the nervous system is, to a large extent, a matter of difficulty and uncertainty. Syphilis is a mimicking disease, its manifestations are more or less imitations of other pathological types; it lacks originality. It is this want of specificity in its symptoms which, by a strange contradiction, but according to an old adage, has gained for it the designation of the specific disease *par excellence*. Of such contradictions many more are to be found in syphilography, and, perhaps, none are more striking than that syphilis has been, and is still, considered a "surgical malady." Syphilography has long been, and still is, considered a part of surgery, although there is scarcely any other disease in the whole range of medicine which is so intrinsically "internal," and so rarely appeals to the skill of the *chirurgeon*. Hutchinson once gave it as his opinion that, "had it not been for the unfortunate tendency to recur and become protracted, syphilis might have remained a surgical malady." Yet, he himself describes it as one of the "specific fevers," and classes it with such diseases as variola, measles, and scarlet fever. It seems to me that, like the "specific fevers," or as we would say nowadays, the acute infectious diseases, syphilis never has been a surgical malady, and that the physician has some better-founded claim to it than the surgeon, who bountifully bestows on him all that has the unfortunate tendency "to recur and become protracted." I do not flatter myself that what I say will have the effect of restoring syphilography to its proper place and quarters. But I wish to give expression to a long-felt grievance arising out of a wrong division of labor.

I now return to the syphilitic diseases of the nervous system which should be relegated to the physician, not only for their unfortunate tendency to be obstinate, but also for the difficulty and uncertainty of diagnosis. Here, more than anywhere else, it is true that the diagnosis of syphilis can not be made from a single symptom, but only from a combination of symptoms, or rather from the evolution of the disease. A causal connection between syphilis, and a nervous disorder can not be established by the report of isolated cases, but only by the consideration of large numbers of cases of the same kind. This difficulty of diagnosis is further increased if we turn from the syphilitic diseases of the nervous system to those called parasyphilitic. The definition given of a parasyphilitic affection is, that it is syphilitic in origin, but not in nature. In other words, that it is caused by syphilis, but that it is neither inflammatory nor gummatous. In the case of nervous diseases, the decision whether the disease is syphilitic or parasyphilitic would, therefore, rest entirely with the pathologist, were it not for certain clinical differences by which their nature is said to manifest itself *intra vitam*. Fournier, the foremost protagonist of parasyphilis, gives the following rules by which to discriminate between syphilitic and parasyphilitic affections:

1. The parasyphilitic lesion is "banal," it is not characteristic of syphilis, it is to be met with outside of syphilis, it is produced by other causes, while the syphilitic lesion, such as a mucous patch or a gumma, is "specific," *sui generis*, and is not to be found in any other disease but syphilis.

2. The effect of antisyphilitic treatment on parasyphilitic lesions is said to be either *nil*, or very slow and incomplete, while in syphilitic affections, it is rapid and complete.

At the Madrid International Congress the value of parasyphilis for the retrospective diagnosis of the disease, was one of the subjects under discussion. I tried to show that the principle underlying the distinction between syphilitic and parasyphilitic affections is not only insufficient, but that it is faulty altogether. In its application to hereditary syphilis, in

particular, it leads to consequences which, by themselves, prove its fallaciousness. But this becomes most evident when this principle of division is applied to syphilis of the nervous system. We have seen that all truly syphilitic nervous diseases are "banal;" there is not one which is specific or characteristic of syphilis, not one which may not be produced by other causes as well. And we have also seen that the inefficacy of treatment constitutes no certain proof of the syphilitic nature of the disease. In fact, in syphilis of the nervous system the chances of treatment depend upon the damage done to the nerve substance by the alteration of the connective tissue, and where such damage has been of considerable extent or duration, the effect of treatment will be practically *nil*. It must be remembered that in organic nervous diseases there is a difference between the anatomical and the clinical cure. Specific treatment may heal the syphilitic processes without any amelioration of symptoms, because the nerve-tissue has suffered beyond repair. In nuclear lesions of the third nerve, for instance, consequent upon syphilitic inflammation, it seems that treatment is rarely of any avail, owing to the tenderness and vulnerability of the nervous elements concerned. In all such cases the effect of treatment, clinically speaking, will be negative, while anatomically it may have reduced the process of cell-proliferation to cicatrization. But not in these cases only is antisyphilitic treatment doomed to be powerless, although directed against a lesion truly syphilitic in nature. Take, for example, those rare cases of acute transverse myelitis occurring in the early stages of syphilis. It has long been observed that these cases of sudden onset have a tendency to run a rapid course, and are rarely checked, even by the most energetic treatment. During a marked secondary rash, with more or less rise of temperature—and while under appropriate treatment—the patient develops, suddenly, all the classical and "banal" symptoms of a transverse myelitis and succumbs, although treatment is pushed to the utmost. The *post-mortem* reveals the diffuse changes in the arteries, typical of syphilis. Cases of this class would have both the characteristics of parasyphilis, viz., banality and refractoriness to treatment, and yet be true syphilis. The greater or lesser completeness of the curative effect, its greater or lesser rapidity, are marks too vague and indistinct to build upon them a differentiation of two classes of affections. With regard to the last point, it has been my experience that, unless some improvement is noticeable by the end of the second week, the chances of a cure, whether partial or complete, are small. This is not a hard and fast rule, without exceptions, but with the beginning of the third week the chances certainly become rapidly less favorable. Incomplete cures are so frequent with true syphilis diseases of the nervous system that with some of them, as for instance Erb's spastic spinal paralysis, they are the rule. On the other hand more or less improvement, and even complete cures by treatment have been reported in cases of parasyphilis, and if we are to accept certain statistics, some parasyphilitic lesions, such as tabes and leucoderma, are more frequently associated with a distinct history of syphilis than even the gumma itself. It is the fault clinical principle upon which the whole distinction between syphilis and parasyphilis is based, that leads us into a maze of contradictions. Between the two we are told there exists an "abyss," yet the same author declares that there is no clear line of demarcation between them, that one gradually and continually passes into the other.

Parasyphilis, if not the great "invention" which it has been proclaimed, is not altogether a bad nut. Besides a large bubble of air, it contains a small, substantial kernel. But this, on closer inspection, turns out to be an old friend dressed and disguised in a neologism. Pathological conditions which follow a certain morbid process, from which they derived their origin, without partaking of its nature, have long been known as the *sequela* of a disease, and have formed a difficult and curious field of investigation for both the clinician and the pathologist. It has also long been known that syphilis, like other infectious diseases, may lead to disturbances of a general, or a local character, degenerative processes. Lardaceous disease, frequently caused by syphilis, was

by its discoverer, declared to be "void of all specificity," to be syphilitic in origin, but not in nature. Cachexia, marasmus, pulmonary phthisis, have long been acknowledged as consequences of syphilitic infection, without being part of it, i. *e.*, notwithstanding their banality or want of specificity.

By some authors the term "quarternary" stage, has been coined for these non-syphilitic after-effects of syphilitic infection, while by others they have been called post-syphilitic, meta-syphilitic, or parasyphilitic. Among these last, the choice of the most appropriate term will rest with the learned Athenian. But the thing to be expressed is of great antiquity. In fact, it may be said of parasyphilis that what is certain of it is not new, while what is known of it is not certain. It is certain that there are pathological conditions, syphilitic in origin, but not in nature; but whether all the pathological conditions which have recently been huddled together under this collective name have anything in common, whether in particular they can ever be traced to syphilis as their source, must, to every careful and sober observer, be a matter of serious doubt. To Hutchinson we are indebted for a happy parallel, illustrating the relation in which the sequela of a disease stand to the disease itself. They follow it, he says, as war is followed by famine. The two things differ *toto cœlo*, yet the one is the cause of the other. Hutchinson looks upon the tertiary stage of syphilis as the sequela of the true infectious disease, which, according to him, is represented by the secondary stage. This position, however, seems to me untenable. Tertiaries most decidely belong to the period of active hostilities, to the true specific manifestations of syphilis; they certainly are syphilitic, both in origin and in nature. To continue the same metaphor, the tertiary residues may be compared to the occupation army, which, after the termination of the actual warfare, still keeps the hostile strongholds, and must be considered as part and parcel of the invading force. With regard to parasyphilitic conditions, the simile seems to apply with particular appropriateness. These after-effects of syphilitic infection are generally explained by the action of the problematical toxins of the missing germ. Like all bacteriological theories of syphilis, this is only patchwork made from scraps of evidence, clinical or experimental, taken from other infectious diseases. Surely, no one to-day will feel inclined to subscribe to the saying of one of the great masters, that "syphilis is the key to pathology." With better right it may be said, that all the keys which pathology affords, have been tried in vain in order to "unbar these locks," behind which syphilis hides its true nature.

Two classes of nervous diseases have been described as parasyphilitic, viz., functional disorders and degenerative processes. Among the former we find neurasthenia, hysteria, and epilepsy; among the latter, tabes, and general paralysis. Of certain other affections, such as hydrocephalus, I shall not speak here, because they belong to the congenital form of the disease, and in this paper I limit myself to acquired syphilis. Nor shall I speak of the psychical disturbances, the true psychoses following syphilis.

There is no definite line of demarcation to be drawn between neurasthenia and hysteria. It is, therefore, practical to treat these sister-affections together. That syphilis may be among their causes, exciting or occasionally, there can be no doubt. But if we look through the long list of *agents provocateurs*, which in a neuropathic disposition may elicit the manifestations of these polymorphous neuroses, we find nearly every other morbid state, whether chronic or acute, general or local. It would certainly not conduce to a clearer understanding of their nature, nor to a more convenient nomenclature of nervous diseases, if exactly the same symptoms, or combination of symptoms, would in every case be called after their exciting cause, with the prefix "para." That influenza, tuberculosis, even a simple cold, may, in the neurotic, be followed by nervous disturbances of various description, every one knows. Yet nobody would speak of para-influenza, para-tuberculosis, etc., of the nervous system. That syphilis may act in the same way "needs no ghost to come from the grave to tell us." But to apply the term parasyphilis to these nervous symptoms seems to me, to say the least, superfluous. It is

true that in some cases they outlast the symptoms of syphilis proper, and show no tendency to disappear under treatment; in other cases, however, they vanish with, or even before, the truly syphilitic manifestations, after a short application of specific drugs. Thus, we should be forced to assume two forms of neurasthenia and hysteria, both caused by syphilis; one syphilitic, one parasyphilitic; one amenable to treatment, the other not. Fournier, in his new treatise, devotes a chapter to the functional disorders of the nervous system during the secondary stage, while he also treats exactly the same affections as specimens of parasyphilis in another work. In the former he recommends mercury as the sovereign, the only and certain remedy; in the other he denounces it to be utterly useless, or at least of very slow and incomplete effect. There is an "abyss," we are told, between syphilitic and parasyphilitic neurasthenia. Such a division is forced and artificial, purely theoretical, of neither practical nor scientific value. Syphilophobia, for instance, a not very unfrequent and often a most troublesome complication of the disease, as a rule, outlasts all manifestations of syphilis, and does not yield to treatment in the least; it may also exist without syphilitic infection; it has, in fact, all the characteristics of a para-affection. But exactly the same is true with what the French call *uréthromanie*, a morbid dread of *la goutte*, which occurs with or without gonorrhea. To speak of it as paragonorrhea of the nervous system because it is "banal," and does not give way to astringents, would be preposterous. Yet functional parasyphilis of the nervous system does not rest on more solid ground. It is the nature of the disease which is said to establish the difference between syphilis and parasyphilis, But what is the nature of a functional disorder? *I do not know of any better definition of a functional disease, than that it is one of which we do not know the organic cause.* If, with regard to organic changes of the nervous system, the pathologist can frequently settle the question whether it is syphilitic or not, he must, of necessity, fail where he has to deal with functional disease. It is idle to speak of the "nature" of a disease, or to make the nature of disease the principle of classification, where the inscrutability of its nature is part of its essence.

That functional disorders may accompany and unpleasantly complicate syphilis, there is no doubt. But the frequency with which this occurs must, to a large extent, depend on national, or rather racial, peculiarities, if we compare the reports of French authors with what we see every day in England. A distinguished French neurologist has expressed his opinion that hysteria, in all its different forms, is as common in England as in France, and that statements to the contrary are rather due to the unacquaintedness of English physicians with the picture of the disease, than to a lesser liability of the English to suffer from it. Such a position is altogether untenable. I think it may be safely said that nowadays the picture of the disease, from slight neurasthenic symptoms to the alarming *ensemble de la grande hystérie*, is well known to British physicians, thanks to the remarkably vivid descriptions by French writers. But there can be no doubt that, in the male, at least, hysteria is much more rarely observed with us than with our neighbors. And as hysteria in general is less frequent with us, it is naturally a rare complication of syphilis. In men it is quite uncommon, but even in women it is not a frequent occurrence; and where it is to be found the causal connection between it and syphilis will frequently remain doubtful. I have for a long time given special attention to this point, and with particular interest sought for the objective symptoms of hysteria in the syphilitic. But the result is purely negative. Never have I found the concentric limitation of the field of vision—this classical feature of the hysterical picture—nor any one-sided anesthesia. To find certain areas or patches of diminished sensibility in women is so frequent that it is of no diagnostic value. After protracted medical examination it is always easy to map out such insular spots. But they are artificial products, due to the overstrain of an unduly-prolonged exploration.

Much has been said on analgesia during the secondary stage. But here again my personal experience is negative. Of

course, if the overzealous scientist gets the better of the considerate physician, and continues his pin-pricking or other experiments for a considerable period, he is pretty sure to find what he wants, partly from mental fatigue of the patient, partly even from exposure of the skin to the air. But if these sources of error are taken into due consideration, as they always should be, analgesia will—with us at least—be found to be a very rare associate of syphilis, and where it exists, to have more the character of a complication, or accompaniment, than of a consequence or sequel. Tables have been drawn up to give with much minuteness the characteristic points by which syphilitic analgesia is to be discriminated from the ordinary, *i. e.*, the non-syphilitic form. But here again the distinctions made seem arbitrary and fictitious. When analgesia appears in a patient of hysterical disposition, as a consequence of syphilitic infection, the symptoms in no way differ from those due to other causes, and do not betray their origin by petty peculiarities of localization, intensity or duration.

[Written for the MEDICAL BRIEF.]

A New Operation for Prolapsus Uteri, with Notes of One Hundred and Twenty Cases.

BY J. INGLIS-PARSONS, M. D., M. R. C. P., M. R. C. S.,

Surgeon to Chelsea Hospital for Women, London. London, England.

In the consideration of prolapse of the uterus, we have to regard three main factors: (1) the giving way of the pelvic floor either by rupture or relaxation and stretching; (2) relaxation and stretching of the uterine ligaments; (3) increased weight of the uterus.

In many cases after parturition there is prolapse, due to relaxation of both pelvic floor and ligaments. With most patients it is sufficient to prescribe rest and astringents, douches, tonics, and perhaps the temporary use of a pessary. If the perineum is ruptured it should be repaired, while the enlarged uterus can be reduced in size by appropriate treatment.

The restoration of the pelvic floor in many cases of minor prolapse gives the extra assistance required to keep up the uterus. But in severe cases it is not enough; a gradual stretching takes place after the operation, and relaxation of the vaginal outlet follows from the continued pressure above of the prolapsed uterus. Of the operations on the pelvic floor, that which I find most useful is to remove a triangular flap from the posterior wall of the vagina; the edges are then brought together, and the usual flap-splitting operation on the perineum follows. I have done a large number of cases like this, and as an adjunct to other treatment for procidentia it is, in my opinion, the best of the various operations on the pelvic floor.

When all these measures have been carried out, there still remain some cases where the prolapse persists in spite of the various measures taken to combat it.

It may be impossible to restore the tone of the pelvic floor. Although by operation we can restore its shape, we can not always prevent it from stretching again. Even when the pelvic floor has entirely recovered both shape and tone, the uterus will still come down.

The fault lies chiefly in the uterine ligaments. There are considerable variations in the strength of these ligaments among women, the explanation for which is probably to be found in heredity. I have seen complete procidentia in a single woman with a perfect pelvic floor and intact hymen. In this patient the pelvic floor was complete, but it could not hold up the uterus because the ligaments had given way. In contrast to this we find patients with complete rupture of the pelvic floor lasting for years, and yet the ligaments are so strong that without assistance they are able to hold up the uterus and no prolapse follows.

When operations on the pelvic floor are not enough, ventrofixation may be tried.

In order to form an opinion of the value of hysteropexy for severe prolapse, we must consider the operation entirely apart from retroversion. For the latter condition I am quite satisfied with the operation, but for severe prolapse I am not, and for this reason: to be of any service in prolapse ventrofixation must be done with firm adhesions to the abdominal wall. Before the menopause, this leads

to complications when pregnancy occurs, and after the menopause the abdominal wall is often so lax that it becomes pouched and is dragged down by the descending uterus. This does not apply to retroversion, because there is much less drag on the abdominal wall, and the uterus being suspended and not fixed, can expand if pregnancy occurs.

The treatment which I bring forward is meant to supplement the measures now in vogue, and will be found useful when they fail.

The general idea of the operation is to strengthen the band within the broad ligaments and enable them to hold up the uterus.

This band, consisting of fibro-muscular and elastic tissue, runs upwards and outwards from the cervix to the walls of the pelvis. It has been more particularly described by Dr. J. C. Webster. (*Researches on Female Anatomy*, page 88), Sir William Turner, Dr. H. Savage (*Anatomical Illustrations of the Surgery of the Female Pelvic Organs*), and others.

We are not attempting to form a new ligament as in ventrofixation, but to strengthen one already existing.

The principle of the treatment is simple, and consists in taking advantage of Nature's reparative powers.

When falling of the womb takes place, the process is gradual and may be going on slowly for months, and even years, before there is much descent. As a consequence there is no stimulus for the formation of the lymph which repairs the ligaments when a joint is dislocated.

I decided to supply this stimulus in the treatment of prolapse of the uterus, and trust to Nature to carry out her part of the work by repairing the over-stretched broad ligaments.

The choice of a reagent to effect this purpose required consideration. It should be antiseptic; the effect should be entirely local, and if any absorption takes place it should be harmless.

Sulphate of quinine fulfilled all these conditions. When injected into the cellular tissue of the arm it appears to be precipitated and causes an effusion of lymph, which remains for some weeks. It has the advantage of being strongly antiseptic, and a tonic to the general system if absorption should occur. A solution is injected into the cellular tissue of the broad ligaments from the vagina.

The uterine arteries and veins lying on the inner side of the broad ligaments are not in the way if the needle is inserted at the right point in the vagina; the same may be said of the ureters; while the outer two-thirds of the lower half of the broad ligament contains no veins or arteries of any size or importance, and can be freely laid open from the vagina without having to tie a single vessel. I say this with conviction, because I had the opportunity of examining this space on occasions when doing other operations. It is necessary to lay stress on this point because many of the illustrations in the text-books give the impression that the space is filled with a plexus of veins.

The operation takes only a few minutes, and is free from risk if done with precision, care and antiseptic precautions. There is no rise of temperature. It is essential that the point of the needle should be within the folds of the ligament and in the cellular tissue.

An anesthetic is an advantage because it insures immobility, but it is not a necessity. The patient is placed in the lithotomy position. The vagina, which has been thoroughly douched for some days before, is washed out with a solution of hydrarg. perchlor. one to two thousand. The rectum has, of course, been emptied as well as the bladder. The posterior wall of the vagina is pressed down with a Sims' speculum, while the anterior is held up by a retractor. Even then, in some of these severe procidentia cases, the extreme dilation of the vaginal walls will allow them to roll together in folds and block the view of the cervix. Under these circumstances two lateral retractors are required as well as the other two. The injection is made on each side through the vaginal wall, taking care that the direction of the needle is perpendicular to the base of the broad ligament and parallel to the long axis of the uterus.

The syringe I employ has a long, straight, rather thin but rigid nozzle, so that when it is passed into the vagina the light is not excluded. The needle is an inch in length and rather thicker than a hypodermic. Before the injection is

made it should always be tested, because the quinine solution is apt to cause corrosion and may snap off short. If the patient has not taken an anesthetic she will hardly feel the prick of the needle, but as soon as the injection of quinine begins some pain is felt for a few minutes, the severity of which varies in different individuals. Perhaps this might be obviated by an injection of eucaine. The operation is now over and should not take more than a few minutes. Before the patient is lifted into bed, the uterus should be well anteverted bimanually. A cup and stem india-rubber vaginal pessary, secured by tapes to a band around the waist, is inserted so as to keep the uterus well up until the effusion of lymph has taken place. It can then be removed, as the uterus at the end of four or five days is held up by the effusion.

The strength of the sulphate of quinine solution is important. If too strong it will cause suppuration, and if too weak it will not give sufficient stimulus to repair the ligaments. It is of importance to see that the solution of quinine is accurately made up. The treatment can not succeed if the solution is not right. For the past twelve months I have used a solution of one in five. The amount which is injected will vary according to the severity of the case; but the average amount which I use is sixty to eighty minims on each side for each injection.

After the operation done under anesthesia most patients have no pain. For the first few days there is a slight aching in the pelvis, which then passes off. Nor is there any inflammation. The temperature usually remains normal. The patient should, as far as possible, lie on her face, so as to throw the uterus forward.

In the consideration of each case an estimate must be formed of the amount of strengthening required to hold up the uterus.

For severe prolapse, such as we meet in private practice, but which has not reached procidentia, one injection of sixty to eighty minims into each broad ligament ought to be sufficient.

Among the working classes, when we have to deal with a patient who has chronic procidentia for many years, enlarged uterus, dilated vaginal walls, overstretched pelvic floor and weak general health, who will have to do hard work and constant standing after the treatment is finished, two or even three injections may be necessary to produce a satisfactory result. Our opinion will also be influenced by the reaction of the patient to the injection. The healthy, well-nourished woman will effuse and organize more lymph than the thin, anemic and exhausted mother of a large family.

The most difficult part of the treatment is to estimate the amount required to keep the uterus up permanently. One injection will always do this for a time, even in the worst cases.

But it does not follow that one injection is sufficient. The amount of strengthening must be proportioned to the strain in each case, and this will depend on the weight of the uterus and the condition of the pelvic floor and the duration of the prolapse and the work the patient will have to do. If she has to stand for ten hours a day in a shop or at the washtub, or lift heavy weights, she will require more injecting than a lady who never does more in the way of exercise than an hour's ride on horseback. Again, unless the patient is kept at rest until organization of the exudation has taken place, the operation will fail.

At the end of four days after the injection the pessary can generally be removed, as there is usually enough effusion to keep up the uterus. On examination per vaginam the effusion can be felt in both fornices. It is firm and resilient, not hard, and feels like a hand passing from the uterus to the pelvic wall. The uterus is held up but not fixed and still has mobility.

If a second or third injection is required, the amount of solution injected is reduced to forty to sixty minims. An interval of at least fourteen days should elapse before a second injection is made.

There can be no doubt that the sulphate of quinine is deposited. None of these patients have ever had the least sign of cinchonism, although as much as twelve grains have been injected at a sitting.

When the effusion of lymph has taken place, the next, a very important point for consideration, is this: What treat-

ment shall we adopt to secure organization and prevent absorption? If an injured joint is kept at rest too long, more fibrous tissue than is necessary for repair of the ligaments is likely to take place, and impairment of movement follows.

On the other hand, if passive movements are practiced at an early date and massage is used to increase the circulation through the injured part, this does not occur; repair takes place and the superfluous lymph is absorbed.

If we apply this lesson to the treatment under consideration, the indications are to keep the uterus at rest as much as possible and restrain the circulation through the pelvis in order to promote organization and avoid absorption. This is done by keeping the patient at rest in the recumbent position. It is never possible to keep the uterus completely at rest, owing to the filling and emptying of the bladder, and the movements of the abdomen in respiration.

The benefit derived by patients with chronic procidentia when the uterus is well held up, although apparent when they are allowed to get up, is more marked in most cases at the end of three or four months. The uterus becomes smaller, owing to the absence of the chronic congestion to which it was before exposed. This is particularly observed in the mushroom-shaped enlargement of the cervix. In several cases I have seen the cervix diminish to half its previous size. At the same time the large erosions and profuse cervical discharge gradually clear up. An improvement also takes place in the vaginal walls. Being held up by the uterus they have some chance of recovering their tone. The minor cases of cystocele and rectocele appear to get quite well, while the severe cases which at first ballooned out of the vaginal orifice on the least provocation are, to a great extent, kept in place by a ring pessary, and contract to a quarter of their former size.

For instance, a patient who had procidentia for twenty-five years, had at first to wear a ring for cystocele, although the uterus kept up perfectly. In May of last year the vaginal walls had quite recovered, and I was able to remove the pessary altogether.

The treatment does not prevent or interfere with pregnancy. Six patients became pregnant a few months after the uterus was restored to its normal position. They were able to do their work for the first seven months, and were delivered of healthy children at full term this year without complications. This was what I had anticipated, because the treatment does not impair the normal mobility of the uterus. Although these patients had to do hard work there has been no return of the procidentia. The uterus still keeps up, although not so well as before they became pregnant.

Of the one hundred and twenty cases that I have operated on only five have relapsed to their former condition; twenty-four cases have been improved, while the other ninety-one patients have remained well and the uterus has been kept in its proper position.

In these one hundred and twenty cases, except four, the uterus came outside the vulva.

Ten years have passed since the first patient was treated by this method. She has since been earning her living as a cook, and in spite of continued hard work the uterus keeps up, although when she came to the hospital it was outside the vulva and extensively ulcerated from friction.

The results by this treatment are, on the whole, very good. Most of the patients have been able to resume work and have once more become useful members of society.

The Treatment of Pulmonary Tuberculosis.

BY W. F. MILROY, M. D.,

Professor of Clinical Medicine and Physical Diagnosis in the University of Nebraska. Omaha, Neb.

The present generally accepted views in regard to the treatment of tuberculosis involve three principal features, viz., rest, fresh air, and forced feeding. The difficulty with this plan is that many persons are not able to submit to this treatment in a thorough way, owing to a variety of circumstances, chiefly financial disability. These things ought to be done as

nearly as possible in every case, for the ideal conditions would be secured, and the nearest approach possible to the ideal should be insisted upon. Since, however, the thorough application of these ideas is impossible very many times, it is still worth while to consider what may be done in the use of other measures.

Formerly, we depended upon various drugs, and the use of cod-liver oil and other reconstructives of that class. I wish to call attention to one remedy, in particular, as, in my opinion, offering something of real value. Some ten or twelve years ago, the late Dr. Pepper, of Philadelphia, called attention to the value of strychnine in large doses in this disease. Acting upon his suggestion, I have made use of the method in a large number of cases. The method, as employed by me, and, in the main, as suggested by Dr. Pepper, is as follows:

The strychnine is given in pill form, beginning with four doses of one-thirtieth of a grain in each twenty-four hours, the administration of the four doses being distributed as equally as can conveniently be done throughout the twenty-four hours. At the end of the fifth day of the treatment the dose is increased, two-thirtieths of a grain being given in one of these doses; the three remaining doses at one-thirtieth of a grain, as before. Five days later, another of the four doses is increased to two-thirtieths of a grain. At the end of each five days the dose is increased, in this manner, until two-thirtieths of a grain are given at each dose; subsequently at the end of each period of five days, the dose is increased by one-sixtieth of a grain, and this periodic increase of the quantity given is continued at the end of each five-day period, until each of the doses consists of the two-thirtieths of a grain, plus one-sixtieth of a grain. All subsequent augmentation of the dose is by the addition of one-sixtieth of a grain.

The indication which I aim to fulfill is to administer this drug until the physiological effects of it are observed in the patient. The quantity necessary to secure this result varies in different individuals, but whether the patient tolerates a large or small amount, it is insisted that the dose shall be pushed to the point mentioned. The evidence of the physiological effect having been reached, which I have observed, consists in muscular contractions seen in one of the three following locations:

1. The muscles of the inferior maxilla, causing a stiffness of the jaw, as patients describe it.

2. Posterior muscles of the neck causing a disposition to throw the head backward.

3. In anterior muscles of the thigh, causing a disposition to lift the feet very high in walking, as if to step over some object.

When any one of these symptoms is observed the dose should be diminished by about twenty-five per cent of the quantity that was necessary to produce the physiological effect which is observed, after which the dose will again be increased, as soon as the contractions of the muscles have ceased, up to a point just short of that which originally produced these contractions. The dose shall then be maintained at that point; but within, perhaps, seven to ten days, it may again be increased, when it will very commonly be found that the amount which before produced muscular contractions will no longer do so, and the dose may again be still further increased.

The point to be borne in mind in this connection, is that a certain degree of immunity to the effects of the drug seem to be established in one who is taking it, and after this has occurred it is important to still further increase the dose, periodically, so as to continually administer the maximum amount that the patient will tolerate.

The physician may be apprehensive lest in crowding this powerful drug in the manner described, he may actually poison his patient. According to my experience, quite a large margin exists between the amount that is necessary to produce the first muscular contractions and the amount that is actually injurious to the patient, so that if care is exercised there need be no danger whatever to the patient in this treatment.

It has always been my practice to explain fully to the patient the nature of the remedy that he is taking and the symptoms that it is important to observe,

and to instruct him to consult me at once, and to diminish the dosage. If the patient is not of sufficient mental capacity to be depended upon to carry out these instructions, I would not favor this mode of treatment, except in cases in which the patient is in a hospital under careful observation.

The effects upon the condition of the patient which I have observed are, in a word, improvement in every symptom in which the patient with this disease may be suffering, viz., with respect to the cough, temperature, the ability to digest food, night sweats, and, in short, the variety of symptoms seen in cases of pulmonary tuberculosis. The quantity which I have administered in one case was three-quarters of a grain each twenty-four hours, for a long period. A friend of mine gave a patient five-sixths of a grain daily for a long period, and to another patient he gave one grain daily for nearly a week without any toxic symptoms.

The effects of strychnine administered to human beings are described as occurring in three stages:

1. The tonic.
2. The convulsive.
3. The paralytic.

The action of strychnine is chiefly upon the nervous system. In its use the aim is to administer the dose to a point just short of the convulsive effect. All of the functions of the body depend for their stimulation upon the nervous system; therefore, if the nervous system is stimulated we find increased frequency and depth of the respirations, increased power of the heart action, with a higher degree of arterial tension, an increase in all the glandular secretions, an increase in the power of the special senses, these being the conditions which are described as representing the physiologic effect of strychnine.

It seems to me that a consideration of these facts offers an adequate explanation for the good results which are seen in the use of this remedy in pulmonary tuberculosis, which is to re-establish a lost resistance and improve the general nutrition of the body.

Multiple Neuritis.

BY FRANK A. ELY, M. D.,

Professor of Physiology and Neurology in Drake University College of Medicine.
Des Moines, Iowa.

There are many diseases of the nervous system which seldom, if ever, come under the observation of the general practitioner. For that reason it seems best, at this time, to consider a subject which is of common interest to both the general man and the neurologist.

Multiple neuritis is a disease which physicians in all lines of work are apt to encounter, since it is usually the result of an intoxication or infection, and the family physician, and not the specialist, is the one who treats most of the infectious diseases.

We have learned, from our study of therapeutics, that certain medicinal agents, for some unaccountable reason, have an affinity for definite tissues of the body. Toxicology and pathology have shown us that certain organic and inorganic poisons vent their spleen upon the tissues of the nervous system, and, as a result, we have the symptoms of these various intoxications referred to that particular system. The toxines of rabies and tetanus are the best examples of this selective intoxication, especially since the micro-organisms do not, as a rule, migrate from the point of inoculation, but produce their effects through the agency of the poisons which they generate.

In taking up a systematic consideration of polyneuritis, our attention is first directed to the etiology, and the watchwords here are poison and malnutrition. Alcohol, lead, arsenic, mercury, silver, phosphorus and carbon-sulphide are among the common causes. Following this procession, we find autointoxication and the various infectious diseases. Among the causes first named, alcohol and lead are particularly worthy of note, since alcoholic neuritis is apt to be mistaken for tabes; and since lead is very apt to manifest its poisonous effects, first as a musculo-spiral palsy, the other nerves coming under its baneful influence later in the disease.

Autointoxication is fast coming to be looked upon as a disease entity, and it is difficult to predict what the future may evolve from this prolific source. Be that as it may, observation has led the writer to believe that not infrequently a multiple neuritis takes its origin in a simple condition of gastritis or gastroenteritis. In such cases, bacterial agents are probably at work, especially the colon bacillus; but the organisms of putrefaction are also largely responsible for the generation of destruction-dealing toxines.

Among the infectious diseases, typhoid, typhus, the exanthemata, diphtheria and influenza are most apt to be followed by a polyneuritis, and in treating these maladies a sharp lookout should be kept in order to recognize the first intimations of nerve degeneration. Syphilis is not infrequently responsible for its development, either as a result of the toxic influence of the syphilitic virus, or as a result of the depraved nutrition which it has occasioned. Tuberculosis, likewise, appears as a predisposing etiological factor. Various cachexias, such as occur in pernicious anemia and cancer, seem to be accompanied by a multiple neuritis, from time to time. As for the period of life, no age seems to be exempt. In children the disease most frequently follows the exanthemata and diphtheria; in the middle-aged adult, alcohol, typhoid, acute rheumatism, influenza and syphilis; while in old age a marked arterio-sclerotic condition lends a helping hand to any of the various toxic influences previously mentioned. It goes without saying, that any occupation necessitating the constant use of lead, arsenic, or any other poison, is a predisposing influence.

Of late years the microscopist, with his acquired facilities for differential tissue-staining, has done much to clear up our hazy ideas with reference to the pathology of multiple neuritis. In the first place, it has been shown that although most of the structural pathology is to be found in the peripheral nerves, the brain and cord are by no means exempt. The conducting tracks of the cord and the ganglionic cells in its gray matter, as well as the cells in the cerebral cortex, have been found to have undergone more or less degeneration, in some cases; hence necessitating our abandonment of the old term, "peripheral neuritis." Notwithstanding the facts just mentioned, the most interesting morbid changes are found in the nerve trunks. Here we observe, as a rule, a degeneration of the axis-cylinders, which is more marked and complete near the nerve extremities, together with more or less hyperemia of the endoneurium and perineurium. It is worthy of mention that the intensity of the intoxication is indicated by the degree of axis-cylinder destruction; that the destructive process, as a rule, decreases from the periphery to the center; and that in a nerve trunk, extensively involved, some normal axis-cylinders may be found by the side of those degenerated.

As for lesions in the cord and brain, many competent observers have reported cases of diphtheritic and alcoholic neuritis in which the ganglionic cells in the anterior gray horns of the cord have been found in an atrophic and degenerated condition; while many others vouch for like retrograde changes in the cells of the cerebrum and cerebellum. The medulla and pons, like the cord, are subject to degenerative lesions, which may involve the nuclei of the cranial nerves. Hence, the frequency with which a polyneuritis, especially of diphtheritic or alcoholic origin, is attended by cranial nerve symptoms.

The muscles which are enervated by the nerves which have become involved in the neuritic process, become more or less atrophied, and there is, in many instances, an increase in the endomysium and perimysium. The muscle fibers are not uniformly involved, indicating the relationship which probably exists between the unaffected axis-cylinders and the normal muscle fibers. In some cases the excessive proliferation of fibrous tissue between the muscle fibers and fasciculi causes a permanent contraction of the muscle, even after the nerves have undergone complete regeneration.

In attempting to portray the clinical manifestations and individual symptoms of polyneuritis, the clinician is confronted by no easy task, since each form of intoxication has some symptoms which are, more or less, distinct and characteristic. Generally speaking, a multiple neuritis

affects both sides of the body at about the same time. The effect may be more pronounced on one side than on the other, and one side may be affected a little before the other; but one limb or limbs of one side are never singled out, leaving the others intact. In short, the disease is accompanied by a symmetrical involvement of the body. An alcoholic neuritis affects more especially the lower extremities, while a lead intoxication pays special attention to the upper. One case of neuritis will be accompanied by symptoms which are largely sensory, while another will show chiefly a motor involvement. The writer has observed a disposition upon the part of many general practitioners to question a diagnosis of neuritis in which the sensory symptoms, especially those of pain and tenderness along the course of the nerves, are wanting, overlooking the fact that many of the most pronounced cases are unaccompanied by any great disturbance of the sensorium:

In dealing with the symptomatology proper, we will first consider the muscular and motor manifestations, which are, perhaps, the most important among the objective symptoms. Few cases of polyneuritis fail to develop a more or less marked paresis in the muscles of the upper or lower extremities, or in both. Complete paralysis is rare, but almost any grade of motor disability may be produced. This paretic weakness begins at the ends of the extremities and gradually involves the whole of the limbs, and may even invade the trunk muscles. The extensor muscles are first involved, and, as a result, we most frequently find foot-drop and wrist-drop among the early clinical signs.

The extensor involvement in the legs causes an equino-varus position in the feet, and an absolute loss of dorsal flexion beyond a right angle. Bearing this in mind, the gait of these neuritic individuals may be easily understood. Upon taking a step, in order to clear the ground with the drooping foot, the thigh has to be well flexed upon the body. The limp, flail-like leg, is swung forward, and the toes and outer border of the foot first come in contact with the floor. A series of these china-doll movements constitutes the "steppage" gait of Charcot. Not infrequently the muscles in the thighs become extensively involved, resulting in almost total ambulatory disability. The motor symptoms in the upper extremities, especially in lead neuritis, are equally worthy of mention. Here the earliest paretic manifestations usually come within the bounds of the musculo-spiral innervation, and, as a result of the extensor involvement, we notice a marked tendency to wrist-drop. Added to this, we may have the claw-hand, produced by the same accompanying involvement of the median nerve. If the neuritis be a severe one, the muscles of the shoulder girdle and, even of the neck, may be affected.

In determining the amount of degeneration which has taken place in the nerves and muscles, the electrical tests are invaluable. At the beginning we may note an increased irritability upon either faradic or galvanic stimulation. This is very quickly followed by a decreased response to faradism, and a change in the closing galvanic stimuli, the anodal closure causing a stronger contraction than the cathodal. It is important to note, however, that even in the most severe cases a complete loss of electrical irritability does not occur.

As in all other diseases affecting the peripheral motor neurons, we find more or less muscular atrophy. In some instances the muscular wasting is very marked, while in others it is so slight that where all the extremities are affected one finds difficulty in distinguishing between a true atrophy and a general emaciation. As a rule, the atrophy is more marked in the leg and forearm, although the arm, thigh and other skeletal muscles may be equally involved.

Among other motor manifestations may be observed tremors, fibrillary contractions, ataxia and mild inco-ordination. The tremor is coarse in nature, is provoked by voluntary effort, and is more marked when the partially-disabled muscle is fatigued. The fibrillary twitchings are similar to those seen in progressive muscular atrophy, and may be stimulated by spatting the belly of the muscle with a paper-cutter, or the handle of a percussion hammer. The ataxia and inco-ordination may be accounted for on the

ground of muscular weakness, although, as previously observed, the tracts of sensory conduction in the cord may be, in exceptional cases, involved.

Because of the lasting, unsightly deformities which they may produce, the contractures are worthy of our special attention. In early paralysis the flexor muscles seem to claim the right of way. This tendency, which is generally abetted by gravity and the natural anatomic relations of the joint structures, allows the hand or foot to fall an easy prey to the contracting muscular fibrosis, and, as a consequence, the foot becomes fixed in the equin-varus position, or the hand assumes an habitual wrist-drop attitude. These permanent contractures may, in a large measure, be prevented by fixation of the affected part in a normal position, until the fibrous contraction has been overcome.

A study of the reflexes in a case of multiple neuritis only demonstrates those symptoms which might be inferred from the pathology. The cutaneous reflexes may or may not be diminished or abolished. Where marked anesthesia affects the parts, the cutaneous reflexes may be lost. As a rule, they are simply diminished. The tendon reflexes, however, are nearly always diminished to a marked degree in the muscles which are affected. The patellar and Achilles reflexes are usually abolished, as are those of the elbow and wrist. The organic reflexes, which preside over the sphincters of the bowel and bladder, are seldom affected. Hence, we find in this a valuable differential point between neuritis and myelitis.

In passing from a consideration of the motor phenomena, we are next confronted by a series of sensory manifestations, which are of equal import and interest. Not infrequently, the first warning which the patient has of the onset of the disease is a sensation of numbness, prickling or crawling in the ends of the fingers and toes, and in the soles of the feet. After a time, the paresthetic sensations become more marked, and gradually invade the extremities as high as the knees and elbows, and, in severe cases, the whole of the extremities and portions of the trunk may also be affected. After the malady has progressed for a time these indefinite paresthesias are replaced by anesthesia and hyperesthesia. In some cases there will be a marked diminution or loss of the tactile, pain or temperature senses; in others, only one of these modifications of the tactile sense may be missing; or the tactile sense proper may show delayed conduction. On the other hand, the pain sense may be augmented to such an extent that the stroke of a pledget of cotton or the contact of the bed clothes may produce great discomfort. At times, also, a tactile impulse may be misinterpreted by the brain, being construed as a sensation of heat or cold. As previously intimated, many general practitioners lay great diagnostic stress upon the presence of deep-seated pain along the course of the nerve trunk, and upon tenderness on pressure, in the same localities. These symptoms are frequently present, it is true, but are not as characteristic as the same manifestations in the isolated neuritides. Not infrequently the pain and the hyperesthesia seems to be more pronounced in the superficial tissues and in the muscles than along the nerve trunks, leading one to suspect the presence of an accompanying myositis. By far the most common and persistent sensory disorder encountered in these cases is anesthesia. The ends of the fingers and toes are the parts first affected, and the last to recover. It has lately been the writer's privilege to see a case of multiple neuritis following typhoid, in which all four extremities were absolutely anesthetic, and in which the greater part of the trunk, as high as the neck, was likewise affected. The motor paralysis, in this case, was coextensive with the sensory; yet the patient made a rapid and uneventful recovery in about six weeks.

Among the organs of special sense, we find the eye coming in for the lion's share of functional pathology in many of these cases. Especially do we find these symptoms following in the wake of a diphtheritic intoxication. As pertaining to the optic nerve and retina, we may find a papillitis, retracted field for white, or modifications of the color fields. As for the extrinsic muscles of the eye, we may find any one or all paretic, producing any one of the various forms of squint. Errors of accommodation, due to paresis of

the intrinsic eye muscles, are exceedingly common, but modifications of the form and reflexes of the pupil are correspondingly rare. It is important for the diagnostician to remember that the Argyll-Robertson pupil is seldom, if ever, found in a neuritis; hence we have in its presence a distinct indication of tabes, in contradistinction to the form of alcoholic neuritis known as pseudo-tabes.

Aside from the special symptoms heretofore mentioned, we find the general nutrition of the body greatly altered, either as a result of the toxic condition, which has caused the neuritis, or on account of the forced inactivity and altered functionation brought about by the neuritis itself. There is frequently a slight elevation of temperature; the bowels and digestive tract become inactive; the heart's action becomes accelerated, weakened or irregular, and the respiratory capacity may become diminished, as a result of paresis of the respiratory muscles. The cutaneous tissues and muscles showed marked atrophic changes. The skin becomes dry and scaly, or, in rare instances, moist and clammy; about the roots of the nails it takes on a reddish, glossy appearance. Its appendages also share in the nutritional disturbance, the nails becoming hooked and claw-like, and the hair dry and brittle.

Among other interesting morbid features pertaining to the disease under consideration must be mentioned the various mental symptoms which are often developed, especially in cases of alcoholic origin. The psychic changes may precede the neuritic symptoms, but more commonly begin with them and increase correspondingly in severity. The patient first shows an alteration in character and temperament; becomes irritable and querulous, is exacting in his demands, and is inactive and disinclined to mental exertion. There is more or less insomnia, and the night hours are spent in agitation and apprehension. After a time, indefinite and changeable delusions may develop, as a result of which suicidal or homicidal impulses may be exhibited. During the day the patient is more quiet, but toward evening the excitement increases. In the more severe cases delirium may be quite constant. In some patients another type of psychosis is developed, in which the patient loses account of time and place, forgets what he has said but a moment before, and tells fabulous tales, which are cut largely out of the whole cloth of his disordered imagination.

Time will not admit of a more detailed rehearsal of these interesting mental phenomena. Suffice it to say that mental derangement may occur in almost any type of neuritis; but, all things being equal, the alcoholic cases constitute the banner class.

In this paper it will be impossible to describe at length the different forms of multiple neuritis, as they take their origin in the various kinds of systemic intoxication. As has been previously indicated, alcoholic neuritis usually affects the extensors of the lower extremities first. The sensory symptoms are more marked than the motor, and not infrequently the ataxic symptoms are very pronounced, making the disease difficult to distinguish from true tabes. In a lead neuritis the extensors of the foream are first affected, causing wrist-drop. The muscular atrophy is usually well marked, while the sensory symptoms are not so pronounced. A diphtheritic neuritis most frequently begins during convalescence. The muscles of the palate and pharynx are primarily involved, and the cranial nerves, including the pneumogastric, may be affecte' as a result of which death may take place. If the muscles of the lower extremities become paretic, the Romberg symptom may be developed. In this type of neuritis sensory disturbance is not marked.

Although the diagnosis of multiple neuritis is not particularly difficult when the disease is thoroughly established, its recognition is frequently not at all easy at the onset. When a history of chronic intoxication has been obtained, and we have added to this a gradually-progressing, symmetrical, sensory and motor involvement of the extremities, accompanied by foot-drop and wrist-drop, a provisional diagnosis of neuritis can be made. When, in a short time, muscular atrophy develops, and the skin about the nails takes on its characteristic glossy appearance, and tenderness of the muscles and nerve

trunks can be excited upon pressure, the diagnosis may be made positively. There are, however, several conditions which may be quite difficult to exclude, viz., poliomyelitis, tabes, myelitis, and hysteria. As for poliomyelitis, we find it occurring more frequently in children, while multiple neuritis is, ordinarily, a disease of adult life. A poliomyelitis is more abrupt in its onset, affects the whole of one or more extremities at once, in place of beginning at the ends and slowly extending toward the trunk, and in a short time the extremity last affected shows signs of improvement, and may have partially recovered before the others have begun to improve. Sensory symptoms are seldom and mental symptoms never observed. In recovery from multiple neuritis the sensory and motor symptoms gradually withdraw from the trunk and proximal portions of the extremities toward the fingers and toes, but the withdrawal, like the invasion, is quite symmetrical. Of the two diseases, poliomyelitis is more frequently followed by permanent deformity.

In distinguishing multiple neuritis from tabes, the examiner will oftentimes experience great difficulty. Among the most important differential diagnostic points should be mentioned the Argyll-Robertson pupil, which is never present in neuritis; the presence of muscular atrophies and reactions of degeneration, which are not observed in tabes; the recto-vesical disturbance, which develops early in tabes, but is observed very late, if at all, in neuritis, and the period of development, which covers years in tabes and only weeks or months in neuritis. To these might be added other distinguishing points, which, however, are of much less value. In stepping the tabetic strikes his heels first, the neuritic his toes and the outside of his foot. The tabetic has a girdle sensation, lancinating pains, and gastric crises; while the neuritic has no girdle sensation; as a rule, no abdominal pains, except from digestive disturbance, and the pain in his extremities is more of a rheumatic ache than the stabbing, shooting pains of tabes.

In discriminating between myelitis and multiple neuritis, we observe in the former a distinct tendency to paraplegia, with girdle pains, retained electrical responses, exaggerated reflexes, recto-vesical disturbance, and a tendency to bed sores, all of which conditions point to a cord lesion, and not to involvement of the nerve trunks.

Last, but not least, among the differential diagnostic troubles, comes hysteria, whose omnipresence brings a sprinkling of white to the clinician's head. Hysteria and neuritis may coexist in the same individual, or the former may simulate the latter. To the skilled observer there should be little chance for error. The psychic pain of hysteria is not confirmed by the facial expression. The anesthesias seldom involve the four extremities, and do not correspond to definite groups of sensory nerves. The deep reflexes and electrical responses are normal, and genuine atrophy is not observed.

Before leaving the subject of diagnosis, it may be well to state that one of the most difficult problems to solve in some of these cases is the origin of the intoxication. Cases of alcoholic neuritis have been observed as the result of the prolonged use of various medicines in which liquor is the chief ingredient. Lead neuritis may follow the continued use of certain cosmetics, to say nothing of the frequency with which it occurs in those who are engaged as painters and decorators. The history of previous infectious diseases should always be brought out and given careful consideration before excluding neuritis.

Having gone quite extensively into a consideration of the symptomatology and diagnosis, it now remains for us to consider, briefly, the prognosis and treatment. Generally speaking, the prognosis of multiple neuritis is good. Most cases recover completely, while others develop post-neuritic contractures and deformities. Diphtherial neuritis is, perhaps, the mildest form, and complete recovery is quite certain if the individual survives the first few days. Lead palsy, itself, is responsible for few deaths, but not infrequently the depraved nutrition of the individual, which has resulted from prolonged poisoning, lays him liable to the ravages of intercurrent diseases. Neuritis of alcoholic origin is the type most frequently followed by death. This can be largely accounted for on the ground that these

alcoholic individuals have a lowered power of resistance, and are usually suffering from organic changes in the nervous system, blood vessels, and liver. Neuritis, following autointoxication, is frequently quite protracted in its course, owing to the difficulty in relieving the digestive trouble, which is the primary cause. When a multiple neuritis begins suddenly and progresses rapidly, there is great danger of pneumogastric involvement. Hence, the prognosis should be guarded. In instances where the progress is very slow, a very prolonged course should be anticipated.

In treating multiple neuritis, our first thought is to remove the cause. If alcohol is the "nigger in the woodpile," put your patient in a hospital and enforce total abstinence, since it has been proven impractical, even in Iowa, to prohibit the maintenance of the woodpile. If lead is the offending agent, it should be eliminated by the administration of iodides, and by increasing the activity of the bowel, skin and kidneys. Change of occupation is, of course, imperative when its pursuance necessitates the handling of lead in any form.

In an autotoxic neuritis the gastro-intestinal tract should be frequently spurred to activity by the use of calomel, castor oil and copious enemata, and the various intestinal antiseptics should be employed, among which sulpho-carbolate of zinc, probably, holds first place.

In caring for the general physical condition of these individuals, it is found that rest is a very important factor. The parts affected should by all means be put at rest. Nutrition may be stimulated by gentle massage, but violent manipulations in the early stages are not to be employed. If contractures appear, the physician should exercise his ingenuity in contriving splints and various forms of apparatus to hold the affected parts in normal positions, and should resort to frequently-repeated passive movements to overcome abnormal contractions. Where patients suffer from considerable pain, the use of opiates and hypnotics may be called for, but should be used very sparingly. During the later weeks of the disease full massage and the interrupted galvanic current should be made use of, the individual atrophic muscles being kneaded deeply to encourage elimination and circulation, and repeatedly contracted by opening and closing the galvanic current. As a rule, after the toxic cause has been eliminated, a general tonic, in combination with cod-liver oil, is very beneficial.

[Written for the MEDICAL BRIEF.]

Hoarseness.

BY J. A. WATSON, M. D., C. M.,

Professor of Laryngology, Medical Department, Hamline University, Minneapolis, Minn.

It is, perhaps, not strictly a scientific method to choose a symptom as the subject matter for a study, and reason backward, as it were, from the symptom, which is an effect widely different to the underlying pathological conditions, which are its causes. It is a method, however, which is not without its uses, and it is hoped, in this instance, that it will serve to impress upon the general practitioner the varying, but unfortunately often underestimated import of the symptom which is the subject matter of discussion. The press of apparently much more serious practical problems, the general practitioner's lack of training and skill in the examination of the organ of voice and the mechanism of voice production, the very great variety of conditions upon which this symptom depends, and the very fact that in the majority of instances the underlying lesion is of but slight importance, all combine to cause a tendency toward the taking of what may appear to be slight risks in this direction, but which, unfortunately, result not infrequently in grave errors and, occasionally, in terrible catastrophies.

The common and important causes of hoarseness, under which term we include for convenience's sake the varying degrees of aphonia, are:

1. Simple acute laryngitis.
2. Simple chronic laryngitis.
3. Diphtheritic laryngitis.
4. Odema of the larynx.
5. Tuberculosis of the larynx.
6. Syphilis of the larynx.
7. Neoplasms of the larynx.

8. Hysterical aphonia.

9. Paralysis of the larynx.

It is, no doubt, true that the throat expert can usually save himself considerable trouble and make an immediate and correct diagnosis of the cause of hoarseness by simple laryngoscopic examination, but the general practitioner, whose opportunities are more limited, and who, unfortunately, often fails to use such opportunities as he does possess, will tread more safely by approaching the case more cautiously, and making careful inquiry as to the history and symptoms before proceeding to the objective examination of the throat. He should closely note the following data, and allow none of them to escape his attention:

1. The duration of the hoarseness prior to the time of examination.

2. Its mode of onset (gradually or suddenly).

3. Whether accompanied by pain, soreness, cough, dyspnea, dysphonia or dysphagia.

4. The patient's family history and personal history; inquire especially whether any specific infection, or whether exposure to tuberculosis or other infectious disease. The occupation and mode of life often have an important bearing on the question.

5. The state of the patient's health prior to and subsequent to the onset of hoarseness; particularly should he satisfy himself as to whether there have been any of the general evidences of syphilis or tuberculosis.

6. The patient's general condition at the time of examination; temperature, pulse, respiration and condition of the nervous system should especially be noted. Evidences of hysteria should not be overlooked. It is not contended that it is necessary always, and at all times, to inquire about each and all of the preceding data, since not infrequently a certain history or symptom, or combination of symptoms, establish so strong a suspicion of some certain condition as to justify an immediate examination of the throat, an examination which may at once clinch the diagnosis, even though the examiner be by no means an expert.

A general adherence to this plan of examination, however, will, in the light of the diagnostic facts stated below, establish, after a little practice, a healthy skepticism of attitude that will minimize the possibilities of error. Having obtained such information as to the data suggested, it is now the physician's duty to examine the throat, especially the larynx, objectively. In this age no general practitioner who is unable to do so is properly equipped for his work. It is not difficult to acquire a degree of skill that will enable one, with a little perseverance, to succeed in eighty-five per cent of his cases, and it may be laid down as an inflexible rule that any physician who allows a case of definite aphonia to persist longer than two weeks without either himself obtaining a clear and sufficiently prolonged view of the interior of the larynx, or referring the case to some one who can do so, is remiss in his duty towards his patient.

1. The hoarseness of acute laryngitis usually appears rather suddenly. It persists seldom shorter than two, and seldom longer than ten days. There is nearly always a history of cold, of wet feet, or of other exposure, or of having lately breathed an atmosphere laden with irritating vapor, or of over-use of the voice. When there is no such history and the case still proves to be acute laryngitis, it will commonly be found that the patient is quite subject to such attacks. There is usually a feeling of dryness or irritation in the throat and a slight cough; there may be a little malaise and, perhaps, slightly elevated temperature. On examination, the mucous membrane of the larynx is seen to be more or less swollen and reddened with enlarged and injected vessels. The cords have lost their pearly white appearance, and are sometimes intensely congested.

2. The hoarseness of simple chronic laryngitis is seldom as marked as that of the acute form. There is usually a huskiness or coarseness in the character of the voice, rather than an actual aphonia; a sudden and more or less frequent breaking of the voice, or loss of tone production for the moment, is, however, a fairly good evidence of the condition. The continued attempt to use the voice, in spite of the condition, often causes a sense of fatigue. Sometimes the voice, though husky on commencing to speak, clears up after a few minutes, and the speaker is able

to continue comfortably. There is often a history of repeated acute attacks. Very commonly, however, there is no such history, the chronic condition having been established gradually. The disease often occurs in singers, public speakers, and others whose occupation causes excessive, prolonged, or improper use of the voice. It will be found that in a large proportion of these cases there is some condition causing chronic stenosis in the nasal chambers, and more or less mouth breathing; again, there are often hypertrophied tonsils or other pathological condition in the pharynx. On inspection of the larynx some hyperemia is to be observed, though the cords themselves are occasionally quite white and pearly; very frequently the mucous membrane is quite thickened, especially the arytenoid commissure and posterior wall of the larynx.

3. It is scarcely necessary to do more than merely refer to diphtheritic laryngitis as a cause of hoarseness, since there are almost invariably, in these cases, such a combination of symptoms as to at once arouse a strong suspicion of the condition, a suspicion that when once aroused is usually easily confirmed by laryngoscopic examination, or, where this is impossible, as often happens in children, by bacteriological examination. Cases of primary laryngeal diphtheria are occasionally seen in which there are no objective appearances in the fauces suggestive of the condition of affairs, but the constitutional condition, the severity of the local symptoms, and the all too frequent appearance of dyspnea, will alone render the diagnosis fairly certain.

4. The hoarseness of edema, except at the very beginning of the attack, is usually lost sight of in the presence of symptoms of over-shadowing importance. These symptoms, especially the dyspnea and the laryngoscopic image, commonly render the diagnosis painfully plain. Every general practitioner should bear in mind the probable circumstances under which edema of the larynx is likely to occur. They are acute laryngitis, but only occasionally and in very severe cases, severe infectious inflammations of the throat, operations about the base of the tongue (the writer had a case occurring in his practice after a slight cauterization of the laryngeal tonsil); tuberculosis and syphilis of the larnyx; Bright's disease.

5. The hoarseness of tuberculosis is usually insidious in its onset. There is a peculiar softness and lack of tone to the voice, differing from the metallic harshness of certain other conditions. There is nearly always pain, or at least dysphagia, but sometimes not until late in the disease, long before which time the diagnosis will probably be made. The time at which pain or dysphagia appears depends upon the time at which the stage of infiltration yields to that of ulceration, and upon the portion of the larynx affected. Involvement of the epiglottis and upper portions of the larynx causes severe and early dysphagia. There are nearly always evidences of primary lung involvement, and the ordinary general symptoms of tuberculosis are seldom absent, especially pyrexia and loss of weight. The mucous membranes of the throat are apt to look pale and anemic; some portion or portions of the larynx are more or less swollen from infiltration, most commonly the arytenoid commissure, next in point of frequency the artenoids, the aryepiglottic folds, the false cords, the true cords, the epiglottis. If the stage of ulceration is reached, the ulcers are irregular in outline, apparently flush with the surface, covered by gray or white secretion, and surrounded by pale mucous membrane. Bacteriological examination of the sputum nearly always reveals the presence of bacilli, except, perhaps, in the very early stages.

6. The hoarseness of syphilis is usually harsher and more metallic in character than the last variety; it is seldom accompanied by much pain or dysphagia, though these symptoms are occasionally marked. The laryngoscopic appearance depends on the stage of the disease. Generally speaking, the mucous membrane has a redder and more inflamed appearance than in tuberculosis. The ulcers are deeper, more regular in shape and surrounded by an inflammatory areola. The history and the effect of treatment clinch the diagnosis.

7. The hoarseness of neoplasms varies much in character and in accompanying symptoms, depending on the site, the size, the stage, and the character of the growth. The presence of a neoplasm may be sus-

pected from the symptoms, but can be determined with certainty only by the laryngoscope. A discussion of the differentiation between the various new growths that are found in the larynx is aside from the purposes of this paper. Suffice it to say that the presence or absence of malignancy should be established at the earliest possible moment.

8. Hysterical aphonia may be diagnosed by the fact of its occurrence in hysterical subjects, by the absence of tuberculous or syphilitic history, and of organic changes in the larynx. One peculiar and diagnostic feature is the fact that while the voice may be completely lost the patient is still able to cough. The laryngoscope reveals the fact that while there is no actual paralytic condition, the cords approximate only imperfectly, and, as it were, hesitatingly; a well-marked chink remaining, in spite of an apparently determined attempt at phonation. If brief approximation occurs it is not long enough in duration to enable the patient to produce a distinct sound.

9. The hoarseness of paralysis usually appears suddenly. It is often quite complete in the early stages, while later the patient may regain, to a certain extent, the power of tone production. In abductor paralysis the hoarseness may be accompanied by dyspnea. A satisfactory diagnosis can be made only by obtaining a view of the interior of the larynx, in which case it will be seen that one cord, or perhaps both, fail to a greater or lesser extent in the amount of abduction or adduction, or of both, in which latter case the cord remains in the cadaveric condition.

Every physician should bear in mind and appreciate the circumstances under which laryngeal paralysis is likely to occur, more especially aneurisms, neoplasms, or syphilitic or tubercular infiltrations, so situated as to involve the fibers of the recurrent laryngeal nerve in any portion of its course.

[Written for the MEDICAL BRIEF.]

Psoriasis.

BY JOHN V. SHOEMAKER, M. D., LL. D.,

Professor of Materia Medica Therapeutics, Clinical Medicine and Diseases of the Skin, in the Medico-Chirurgical College and Hospital of Philadelphia. Philadelphia, Pa.

The pátient under discussion in this article is a typical case of psoriasis of five years' standing. This disease is usually defined as a chronic inflammatory cutaneous disease, characterized by an outgrowth of the epithelial layers of the skin, and generally appearing as slightly-elevated, round and reddened patches of various sizes, covered with dry, white scales.

In order to ascertain the probable cause of this man's trouble, we have taken a rather careful history, which reads as follows:

Mr. D. A., aged twenty-six years; nativity, America.

Chief Complaints.—Pain in the limbs at night, especially so whenever he had been exposed to rain or dampness during the day. Headache, anorexia, flatulence and constipation.

Family History.—His parents are both living and well, except the father has chronic rheumatism. One brother died in infancy. Two brothers and three sisters are living and in good health. Accordingly, to his knowledge, there is not one in the family who had ever been afflicted with the same disease. The family history is also negative as regards cancer and tuberculosis.

Previous Personal History.—When he was a child he had whooping cough, diphtheria and scarlet fever, rheumatism at the age of sixteen years, and typhoid fever at the age of twenty-two years. Denies venereal diseases.

Social History.—He is single; lives with his parents.

Occupation.—Carpenter.

Habits.—Drinks from three to five glasses of beer daily. Chews tobacco excessively, but does not smoke. He is a heavy eater, especially of meats and pastry.

Present Illness.—Five years ago he had a severe pain in his right elbow joint. In a week's time after the severe pain in the elbow joint, a small red papule appeared on the extensor surface, near the

elbow, on the right forearm. There was slight desquamation over the surface of the papule and the skin around it. More papules developed near the first papule, which coalesced and formed the present area of infiltration with desquamation. Soon similar patches were found on the scalp and back; the knees and legs were also gradually involved with characteristic patches of infiltrated skin. The involved parts constantly annoy him by an itching condition, so much so that occasionally at night he is unable to sleep.

Physical Signs.—A general examination shows a male, five feet eight inches tall, weighs one hundred and fifty-two pounds, is muscular and well developed. The skin is normal in appearance, except the extensor surface of the forearms, legs, and on the back, where numerous areas of infiltrated skin exists, covered with dry, white scales. Around the infiltrated condition of the skin are many reddish papules, also covered with white scales, and in many instances are in the process of coalescing. The patient's tongue is coated heavily and his breath is very offensive. The hair is dry, coarse, and falls out freely, showing an abnormal state of the skin and its glands. The lymphatic glands appear normal, and nothing abnormal can be elicited over his chest and abdomen.

Diagnosis.—The diagnosis of psoriasis in this patient is easy, because of the chronicity of the affliction, and from the history of the onset. It appeared as a small, reddish papule, became covered with the characteristic white scales; other papules followed on the extensor surface of the extremities, and on the back, which coalesced and formed thick, infiltrated, desquamating areas of the skin.

Psoriasis usually attacks the extensor surfaces of the body; begins as a papule, followed by many more, which coalesce and form sharply-defined patches, as just described. An eruption of the skin presenting the symptoms, the onset, the duration, and the course, as in this patient, could not possibly be due to any other affection.

The diseases of the skin which psoriasis often most resemble are eczema squamosum, syphilis, and seborrhea sicca, but the differential points of these affections with psoriasis, as tabulated below, will readily assist in making a correct diagnosis:

Psoriasis.	Eczema Squamosum.
(1) The primary lesion begins as papule, covered with whitish scales.	(1) The primary lesion begins as an erythematous patch, a vesicle pustule or moist spot.
(2) Itching slight, rarely intense.	(2) Itching intense.
(3) Affected areas, sharply defined.	(3) Affected areas gradually fade into healthy skin.
(4) Areas occur both large and small, and are usually round.	(4) Areas are large and irregular.
(5) Involves with preference the extensor surfaces.	(5) Involves with preference the flexor surfaces.
(6) The lesions often remain unchanged for months.	(6) The lesions rapidly change.
(7) Eruption is always dry.	(7) Eruption usually is moist.
(8) Areas are covered with many white scales.	(8) Areas are covered with small yellowish scales or with crusts.
(9) The course is chronic.	(9) Course is either acute, subacute or chronic.
Psoriasis.	**Syphilis, Squamous.**
(1) History negative.	(1) History of primary lesion.
(2) History of rheumatism, gout or gastro-intestinal catarrh.	(2) History of sore throat, syphilitic fever and other concomitant signs.
(3) Extensor surfaces of arms and legs nearly always involved.	(3) Extensor surfaces of arms and legs, rarely if ever involved.
(4) Lesions regular in outline.	(4) Polymorphous arrangement of lesions.
(5) Scales are shining silvery-white and abundant.	(5) Scales, dirty yellow and few.
(6) Itching slight.	(6) Itching entirely absent.
Psoriasis.	**Seborrhea, Sicca.**
(1) Eruption in areas of entire scalp.	(1) Eruption usually involves the scalp, over the top of the head only.
(2) Scales dry and silvery-white.	(2) Scales yellowish, fatty and greasy to the touch.
(3) Scales consist of epithelial cells.	(3) Scales consist of dried sebum.
(4) Base of eruption is inflammatory and infiltrated.	(4) Base of eruption is anemic.
(5) Eruption also over the body and extremities.	(5) No eruption over the body.

Pathology.—A section of the involved skin, under the microscope, shows a hyperplasia of the mucous layer, and of the normal constituents of the rete malpighii. The increase occurs chiefly in the intercapillary portion of the layer, which, growing downward, gives the appearance of increased size, which is not found to be increased upon close examination. In the advanced stages of the affection, the superficial blood vessels of the corium become dilated, migration of the white corpuscles follows, and the connective tissue and the blood vessels of the corium become the seat of round-cell infiltration, which, together with effused serum, di-

vides the connective tissue into open meshes. There is no involvement of the sebaceous and sudoriferous gland, but there is hyperplasia of the external root of the hair, extending into the cutis.

Etiology.—Psoriasis is as common among the wealthy as among the poor, and in all walks of life. I believe that gout and rheumatism and local irritation to the skin, in those predisposed to the disease by some constitutional condition, are the chief etiological factors. Some claim it to be hereditary, and to follow scrofula, syphilis, and other constitutional diseases, which leave the blood in an impoverished condition. My knowledge and experience in treating the disease does not warrant the belief of the microbic theory as the cause of the disease.

Treatment.—This disease, by many physicians, is thought to be incurable, and probably is so in their hands, because they are not persistent nor rigid enough with the patient in following out the treatment. The disease is curable, but it often requires a most persistent and skillful treatment for months, and sometimes for years. Careful attention must be given to hygienic measures, as well as to the external and internal medication. The physician's aim should first be to seek the cause and remove it.

Treat the cause, whether it be rheumatism, gout, or gastro-intestinal catarrh, and remove it, if possible.

In this patient I believe the chief cause of the trouble is due to his rheumatic diathesis. He gives a history of having had rheumatism, and at present has pain in his limbs and joints at night. His tongue is coated, but I do not think that he has much disturbance of the gastro-intestinal canal. However, I will begin his treatment with a tenth of a grain of calomel every half hour for fifteen doses; the following morning he will be requested to take an ounce and a half of a saturated solution of magnesium sulphate. After his bowels have been thoroughly emptied I shall prescribe a capsule containing:

℞ Olei Gaultheriæ.....3 minims.
Sulphuris Precipitati .....3 grains.
Phenylis Salicylatis .....2 grains.

Misce, fiat capsula No. 1. Mitte No. 30. Sig.: One capsule four times daily for three (3) days, then two capsules four times daily.

Externally he needs a stimulating ointment to the parts affected. Salicylic acid in combination with mercury, is one of the best applications to lessen the infiltration, and stimulate the skin to its normal functions. Therefore, I will give him an ointment containing:

℞ Acidi Salicylici.....1 drachm.
Unguenti Hydrargyri Nitratis... ½ ounce.
Unguenti Aquæ Rosæ..... ½ ounce.

Misce, fiat unguentum. Sig.: Apply locally to the affected condition of the skin, twice daily.

Of course, medicine alone, without attention to hygienic measures and diet, will not cure these patients. The functional activity of the skin, alimentary canal, and the kidneys should be increased, so that the blood may be depurated and oxidation promoted. The bran baths are especially valuable in psoriasis, to soften the skin and loosen the scales. From two to three pounds of bran to a water tub half full, is sufficient.

The diet must be plain, well-cooked, and easily digestible. The excessive use of coffee, tea and highly-spiced food must be avoided. Alcoholic beverages of all kinds is also interdicted. The kidneys and bowels must be kept active by appropriate diuretics and laxatives.

1519 Walnut Street.

[Written for the MEDICAL BRIEF.]

A Few Words Concerning Post-Partum Hemorrhage.

BY O. S. VINLAND, M. D.,

Professor of Anatomy and Venereal Diseases in the Denver Homeopathic Medical College.
Denver, Colo.

Despite the statement of some writers that *post-partum* hemorrhage does not occur in well-managed cases, the fact remains that it does occur not infrequently, and under most careful management.

It is believed that chloroform is a predisposing factor, but this is not borne out by the writer's experience. In four recent cases of *post-partum* hemorrhage chloroform was used in one case only. In other cases, where that anesthetic was used to complete narcosis, hemorrhage did not occur. Undoubtedly the most usual cause for this accident is retained parts of the secundines.

Too hasty delivery of the placenta, I believe to be a cause for *post-partum* hemorrhage. The reason for it would seem

to be the sudden emptying of the uterus before it has had time to react from its effort in expelling the child. Other causes are numerous. In the four cases mentioned, chloroform, being used in one, may be ascribed as the cause.

In this case, a primipara, aged thirty, there was some pelvic deformity. The child was unusually large and labor was difficult and protracted. The patient was nervous and anemic. Chloroform was used extensively, at intervals, for about ten hours, although there was never profound narcosis. In this case I believe that chloroform was a predisposing factor, in that it aggravated the relaxed condition of the uterus, caused by the prolonged and difficult labor. Primary hemorrhage was very profuse and severe, and occurred immediately following the expulsion of the placenta.

In the second case, a primipara, aged twenty-nine, well nourished and in perfect physical condition, the labor was not tedious and, although the child was very large, no anesthetic was used. Hemorrhage was neither severe nor profuse. The cause could not be ascertained.

In case three, a primipara, aged twenty-four, labor was normal, no anesthetic used. Hemorrhage was profuse, and accompanied the expulsion of the secundines. No visible cause.

Case number four differs from the others. Labor was too quick. The membranes were torn in several places, making it difficult to determine whether or not all was passed. The nurse was instructed how to watch, closely, for symptoms of retained parts. About two hours after labor a severe hemorrhage came on, which nearly exsanguinated the patient. The nurse succeeded in controlling it, however, by following the instructions given. After eight hours the woman passed a large blood clot, in which was imbedded a small strip of membrane. I ascribe the cause of this hemorrhage to that little strip, which strip came nearly causing the patient's last journey.

In three of these cases the management was similar and the greatest care used. In the fourth, there was no time for any preparation, as expulsion of the head took place just as the physician arrived, and no nurse was present. While chloroform may have been the predisposing factor in the first case, I can assign no cause for hemorrhage in the two. These very few cases hardly warrant one in drawing conclusions, yet in my practice I have had patients of, apparently, similar constitution, and cases of labor more protracted than those in which the hemorrhage occurred. There must be some constitutional tendency other than hemophilia.

All physicians should be prepared to deal promptly with *post-partum* hemorrhage, especially secondary hemorrhage, and, as a precaution, the physician should always remain for at least one hour after the delivery of the secundines. He should give careful instructions to the nurse regarding the management of hemorrhage, before he leaves. Unless the nurse is competent to deal with such an accident the patient might bleed to death before the doctor could return.

When hemorrhage does occur, the patient should be placed in the Trendelenburg position. At once the physician or other attendant should make pressure forcibly upon the lower part of the abdomen, immediately above the pubic bone, with the outer edge of one hand, in order to compress the lower part of the uterus. This pressure will stop the bleeding almost instantly. With the other hand the uterus is kneaded, to cause contraction. After the immediate hemorrhage has been controlled, the physician must determine whether any of the placenta has been retained, and if so, remove the same. Keep up a gentle massaging, or kneading, of the uterus to insure proper contraction and expulsion of all clots. Of internal remedies each physician has his pets, but ergot or its derivative, such as ergotin, are most universally resorted to in arresting hemorrhage. Other measures, such as the ice bag over the uterine region, injection of hot water into the uterine cavity, even packing the same cavity, and others, may be tried when the others fail, but they should not fail.

The readers of this little article will find nothing new. But, of what has been written some points should be deeply impressed on the physician's, especially the "beginner's," memory.

The points are: Do not assist in removing the placenta too soon, nor too suddenly. To avoid this, remember this rule —make more pressure on the uterus above than you make traction on the cord below. Take plenty of time to find all the secundines; if torn, try to match them together. If a piece be missing, "go for it!" Stay with the patient about one hour after delivery, during which time you give the uterus almost your entire attention, massaging or kneading. The method of making proper pressure is important, in existing hemorrhage. Do not forget to instruct the nurse, in every case, how to manage the accident, nor to leave some form of ergot with her.

Nothing has been mentioned concerning the after-treatment of *post-partum* hemorrhage. In moderately severe cases nature quickly restores the patient, but in very severe ones she is in need of help from outside means. Were it not so difficult to perform, transfusion should be resorted to in all cases of much loss of blood.

The other treatment, which every one can carry out, is to furnish the patient with a liberal, highly-nutritious, liquid diet. Good port wine or grape juice are helpful.

The writer mixes one drachm of the mother tincture China (sulfate of quinine) with about five ounces of water, of which mixture a teaspoonful is given to the patient every hour for about thirty-six hours. The high saline enemas should be given at intervals of a few hours.

Iodine Oil.

BY EDW. H. SHIELDS, M. D.,

Professor of Dermatology in the Miami Medical College, Cincinnati; Dermatologist to the Jewish Hospital, etc.
Cincinnati, Ohio.

During the past ten years I have tried to improve upon some of the various pharmaceutical preparations used in the treatment of skin and venereal diseases; not because they were not efficacious, but because I thought that many of their objectionable features could be removed, enabling me to obtain better and easier results, both for my patient and myself.

The first preparation experimented with was mercurial ointment. The only drawback to this preparation, as obtained from the druggist, was that it was often rancid, and its use is followed by a folliculitis, or an eczema. Second, it requires a long time to properly apply or to rub in from four to six grams. As a substitute for fat I am using goose fat, which, as you know, is very rapidly absorbed, and an ointment with this material for a base will shorten the time of treatment at least fifteen to thirty minutes. This is something that must not be lost sight of, because all patients find this method of treatment very tiresome. As the melting point of goose fat is very low, it can not be used as a base for mercurial ointment without an addition of wax or paraffine, and as an addition of these substances would greatly interfere with its absorption, I have modified it slightly, without the addition of any new substances. This fat contains about forty per cent of stearin, and by freezing the fat it becomes solid. It is then placed in a filter press and the oil expressed until only ten per cent of oil remains. The residue will be found of a suitable consistency for even a summer ointment, without the addition of wax, etc. I now add to the fat one per cent of carbolic acid, which keeps it sweet. With this fat the ointment is made in the usual manner.

To summarize its advantages, I can state:

1. It is very rapidly absorbed.
2. It requires less time for its application.
3. It is soothing to the skin and is less irritating than other mercurial ointments.
4. It requires less ointment when this base is used.

Having had such success with the mercurial ointment, I now began with iodine. I desired a solution of iodine that would not be irritating, and so experimented with the tincture of iodine, but abandoned it. Having a suitable residue for my ointment base, I made a solution of oily iodine, five to one hundred, and was surprised to find a perfect solution. I then attempted a one, ten, twelve, fifteen, eighteen, twenty-one, twenty-two, twenty-three,

twenty-four and twenty-five per cent solution, and though I have not tried a stronger solution, I think that with great care of technique a stronger solution can be made, but as I did not think that greater strengths possessed more value, I carried my experiments in this direction no further. What I have said seems very easy and simple, but the technique which I employ is quite complicated. First, you must have pure, sweet goose fat, taken from the belly of the goose. This is then placed in a glass jar and rendered, the temperature never being over 190° F. The liquid fat is poured off and again heated to 190° F., and the water allowed to separate and flow to the bottom of the jar. The fat is then drawn off and cooled. Up to this stage the fat has not come in contact with any metal. The oil is now frozen to a low temperature and placed in a filter press, whereby all of the stearin is removed. During the early experimental stage I used a suction filter, but, owing to the great loss—being able to obtain only three hundred out of two thousand grams of fat—I abandoned this method. The object of exercising such great care was to increase the solubility of the iodine, and to prevent the contamination with iron. When the above process is properly carried out, we have, as a result, a true oily solution, which is never more than a definite quantity of iodine dissolved in a definite quantity of oil.

It is a well-known fact that some of the essential oils will dissolve iodine, but in the process the iodine is changed, and we have a new salt or combination formed. The principal desiderata of an iodine solution for both internal and external medication is:

1. It must contain iodine in sufficient quantity to produce the physiological effect.
2. It must not irritate the gastro-intestinal mucous membrane.
3. It must be easily assimilated.
4. It should not be changed in its composition before it is ready for absorption.
5. It must be a parasiticide.
6. It must be easily and rapidly absorbed.
7. It should not stain the tissues.
8. It should require small doses.
9. It must be in a convenient place for administration.
10. It should not be depressing in its effects.
11. It must be in such a form that it can be taken at any time, regardless of whether the stomach be full or empty. These requisites I shall now take up seriatim:

The full physiological effects are noticed in a very short time.

The iodine oil is readily assimilated, being found in the urine half an hour after its ingestion.

It does not irritate the mucous membrane of the stomach, because each molecule of iodine is enveloped in oil.

It contains free iodine, therefore it is a parasiticide.

Inasmuch as it is found in the urine one-half hour after its ingestion, and within an hour when the oil is rubbed into the skin, demonstrates beyond a doubt that this preparation is rapidly and easily absorbed.

It does not stain the tissues, and small doses are required.

It is in a convenient form for our patients to carry with them, no vehicle being required.

It is not depressing. The usual salts of iodine are often depressing.

It can be taken at any and all times, regardless of the stomach being empty or full. The only exception being that the stomach be free from alcohol, otherwise a little of the tincture of iodine will be formed, which, as you know, is not desirable.

After considerable experience with these new preparations, having used about ten thousand capsules, I find that the dosage is from ten to twenty-five minim capsules per day.

5 West Eighth Street.

With this I wish to express my thanks for the receipt of your BRIEF promptly for the past three years, and renew my subscription for 1907. My family, as well as myself, find the BRIEF a very essential and instructive book, not only for the doctor, but for all those that desire to study the care of the human body. As such I highly recommend it to all interested. Wishing you success.—DR. F. W. ST. CLAIRE, Chicago, Ill.

The Third Stage of Labor.

BY WILLIAM B. DOHERTY, M. D.,
Professor of Obstetrics, University of Louisville.
Louisville, Ky.

The third stage of labor is the placental stage, or that of the afterbirth, which begins after the expulsion of the child and terminates with the delivery of the membranes and placenta. By contraction and retraction of the uterus the area of the placental site is diminished, the villi or spongelets of the placenta are pressed together and the placenta separated from the uterine wall. Whether it is detached by being folded upon itself and forced down in the longitudinal diameter and delivered edgewise, or in the form of an inverted umbrella, is a question that has given rise to some controversy, but the majority of authorities believe in the former mode of expulsion, and that the latter occurs only when traction is made on the cord. In the majority of cases no procedure or manipulation of any kind on the part of the physician is necessary for the delivery of the placenta, as nature usually does her duty in securing and maintaining uterine contractions which expel it and prevent hemorrhage.

After the birth of the child the uterus may be felt in the hypogastric region as a firm ball. In such cases the woman is perfectly safe, and the obstetrician who is in a hurry and hastens the delivery of the placenta by pulling at the cord, or introducing his hand into the vagina or uterus, does a great wrong, which may result in hemorrhage, sepsis, or dislocation of the uterus. In tedious labors, or manipulative, or instrumental cases in which chloroform was administered for some time, there may be inertia and atony of the muscular fibers, so that the uterus is slow to contract efficiently. If, instead of the feel of a hard ball, like a cricket ball, the uterus appears soft, relaxed, and boggy, it should be stimulated to contract, and be delivered by the Dublin method of expulsion, which consists in gentle kneading, grasping and pressing the uterus downwards and backwards during a pain. The placenta may be detached from the uterine wall and lie in the lower segment of the uterus and be retained, owing to temporary paralysis of the uterine muscles, or inability of the lower uterine segment to maintain its normal condition of distention. Then it becomes necessary to introduce the sterile hand, when the edge of the placenta may be felt protruding at the cervix. One-half hour's time should be devoted to the delivery of the afterbirth by the Crede or Dublin method before the hand is introduced. Traction on the cord should be avoided. Hour-glass contractions do not occur in recent years so frequently as formerly, owing to the fact that ergot is scarcely ever administered, if at all, before the womb is emptied. It is exceedingly rare to find this condition if traction on the child or cord is avoided, and the use of ergot dispensed with.

The afterbirth, in cases of hour-glass contractions, is incarcerated above Bandl's ring, and the contracted fibers of this ring must be dilated by the fingers of one hand, while the other hand is placed on the abdomen and used to express the placenta. Adherent placenta does not occur unless there has been a previous endometritis.

A dose of ergot should be administered after the termination of the third stage, particularly in tedious labors, and, also, when chloroform was administered.

Medical Jurisprudence.

BY FRANK S. DUNSHEE, LL. B.,
Professor of Medical Jurisprudence in the Medical Department of Drake University.
Des Moines, Iowa.

Medical jurisprudence is properly defined as that science which applies the principles and practice of the different branches of medicine to the elucidation of doubtful questions in courts of justice.

The ground upon which the physician and the lawyer meet is the court room and the coroner's inquest, and similar occasions wherein the court asks the opinion of enlightened physicians upon questions unfamiliar to the court and jury. Among the questions which are investigated upon such occasions, for example,

are the effect of poisons upon the human system, whether or not cases of poison were voluntary or criminal; questions of whether blood stains are animal or human; questions of insanity; questions of feigned diseases; questions of personal identity; questions of rape, abortion, paternity, sexual disability, and a large number of other subjects upon which physicians are much better informed than lawyers.

Ordinarily, a witness in a court of justice testifies solely to questions of fact, matters which he has seen or heard or acquired otherwise through his senses. He is under no circumstances permitted (unless called as an expert) to give an opinion. His duty is to lay the facts, concerning which he is questioned, before the jury, and permit the jury to draw the necessary and proper inferences from those facts.

The expert witness, on the other hand, is called for the sole purpose of giving his opinion relative to the effect which is to be attributed to the facts already in evidence. For example, the evidence already in court may show that the patient was suffering from severe spasms at the time of his death. The unprofessional witness may be able to describe minutely the various symptoms and occurrences surrounding and leading up to the death, but, without professional assistance, is absolutely unable to explain what he has observed, through ignorance of the medical phase of the subject.

The physician is called as an expert. The symptoms and occurrences under investigation are described to him, and he is asked to state, not a fact, as is the case with the ordinary witness, but his opinion growing out of the facts which have been placed before him. It may be that upon the opinion of the medical man will depend the question of whether or not the prisoner shall be convicted of murder; whether or not an insurance company shall escape liability to pay life insurance on the ground of suicide; whether or not a practitioner of medicine shall pay heavy damages for having administered a poison negligently and unskillfully.

In fact, the science of medical jurisprudence has become a most important factor in aiding the courts of the country i trials of causes. The importance of th testimony of medical experts will becom more apparent when I say that there scarcely a personal injury case resultin in damage, no matter in what way r ceived, but that it is absolutely necessar in order to determine the extent, as we as the effect of the injury, to call medic expert testimony in order to have th facts of the case properly placed befor the jury, so they may determine whethe the injury is temporary or permanent wnether it will affect the future ability o the person injured to earn a living, o whether the effect of the injury will b greater or less as the time goes on.

One of the most important subject which physicians are called upon to ex plain in court, is that of insanity. I cases of the execution of wills, deeds an contracts, when or where the ments soundness of the person executing suc instruments, or the capacity of such pe sons is called in question, the facts wil be laid before you, and you will be aske for an opinion as to whether or not th person in question was of sound mind.

While traces of this science may be dis covered among the earliest records of civ ilized society, yet, as understood and prac tised at the present time, that is, the ex amination of physicians as experts upo the trial of causes, the science dates a late, probably, as about the fifteenth cen tury.

It was never ordained that physician should be examined in trial until afte the Middle Ages, and we are indebted t Emperor Charles V, of Germany, for th first public enactment to this effect. I the celebrated criminal code framed b him at Ratisbon, in 1532, and which i known by the name of the Caroline Code it is ordained that the opinion of medica men shall be formally taken in every cas where death has been occasioned by vio lent means, such as child-murder an poison, wounds, hanging, drowning, th procuration of abortion, and the like The publication of such a code very nat urally awakened the attention of the med ical profession, and summoned numerou writers from its ranks.

Simplest and Safest Method of Amputation of the Vermiform Appendix.

BY EMORY LANPHEAR, M. D., PH. D., LL. D.,

Formerly Professor of Operative Surgery in the Kansas City Medical College and Professor of Surgery in the St. Louis College of Physicians and Surgeons.
St. Louis, Mo.

It seems strange to me that so much is written and said about such a simple thing as the proper method of removing the vermiform appendix. Queerer still is the common practice of tying a string around the base of the appendix and then "inverting it" (rather, burying it)—as well expect obliteration of the urethra by tying a string around the glans penis; mucous membrane will not unite with mucous membrane. The plan I have followed for years is simplicity itself, as follows:

Draw the cecum well into or beyond the abdominal incision and carefully surround with gauze. Catch the meso-appendix close to the cecal attachment of the appendix with hemostatic forceps, and grasp the serosa of cecum with another forceps, about a half inch away from the appendix. With scissors cut the appendix out, taking with it a small part of the cecum (much of it, if necessary, in order to get well into intestinal tissues free from inflammation).

This leaves simply a hole in the side of the gut, to be closed just like any other incised wound of intestine.

With two or three (or more if the resultant hole is large) silk or linen sutures through the musculosa and mucosa, only, the slit is sewed together, carefully; then the serosa is brought over the line of sutures by a row of ten-day chromicized catgut stitches, No. 1 gut being best. If there seems to be any weakness in this line of sutures the meso-appendix is to be brought up and sewed over and around the intestinal wound, as an additional barrier against leakage.

The cecum is then dropped and the abdominal incision closed.

This operation, of course, is not applicable to cases which have gone on to formation of abscesses; but will be found to be the most simple and safe mode of performing interval operations, as well as removing the appendix in catarrhal inflammation, or as prophylactic appendectomy in the course of abdominal section for other troubles.

Syphilis of the Eye.

BY CHARLES J. LIDIKAY, M. D.,

Professor of Ophthalmology in the University of Kansas.
Kansas City, Kan.

Syphilis attacks the eye as readily as any other part of the body, and unless properly and promptly treated and controlled, results in partial or total loss of vision. No part of the eye is exempt from this dread disease. The anterior parts of the eye are, usually, most affected in primary or acute conditions of syphilis. The posterior parts are more frequently affected in secondary and tertiary forms. The most frequent and one of the most disastrous conditions to vision is syphilitic iritis.

More than one-half of all cases of iritis are caused by syphilis, the percentage ranging from sixty to eighty-five of all cases. It is usually unilateral, but in fifty per cent of all cases ultimately becomes bilateral. It occurs more frequently in males than in females, owing to the more active occupations of the former, and occurs most frequently in early life. The affected iris is of a dull hue, as compared with the other pupil. It is sluggish to light, and may become attached to the anterior side of the lens capsule. This causes the lens to dilate irregularly under the use of atropin.

In serous iritis there is the exudation of a serous fluid, which forms a delicate film on the posterior surface of the cornea, and the anterior face of the lens, and there is increased intra-ocular tension. The pupil is contracted; glaucoma may eventually result.

In parenchymatous or gummatous iritis we have attachments formed between the lens and iris that are firm and unyield-

ing. We may have gummata forming on the iris; these may grow to such an extent as to push out through the cornea and destroy the eyeball. We may also have pus in the anterior chamber.

The symptoms of iritis are: Lachrymation, pain, photophobia, circum-corneal vascularization, discolored iris, and contracted pupil.

Acquired syphilis is one of the most frequent causes of retinitis. We have plastic, serous and parenchymatous inflammations of these tissues. The differential diagnosis of the different forms is difficult. By the aid of the ophthalmoscope we detect increased vascularity, ecchymosis, opacities, edema, and appearance in the fundus of the eye of whitish or yellowish spots. These spots appear either diffused or circumscribed. In the former the entire retina is clouded and slightly gray, with spots in region of the macula that are of a deeper gray. In the later stages these spots usually take on more pigment, and the retina becomes darker. The circumscribed form consists of a large white exudate, usually near the macula, or near a large vessel. This later turns to a bluish white scar, which may, by contracting, cause detachment of the retina. We may also have circumscribed gummata of the retina when there are retinal changes.

When we have syphilitic retinitis, the optic nerve usually has a pinkish color at its point of entrance. It is slightly edematous and surrounded by distended vessels, or it may be hidden from view by plastic deposits upon the surface, or by a cloudy vitreous humor. When the optic nerve or vitreous are affected with syphilis it is, as a rule, due to the extension of that disease from the retina or choroid. They are both rarely the seat of a primary syphilitic affection.

We sometimes have an episcleritis, beginning with pericorneal hyperemia of dull, reddish hue, with few if any subjective sensations. In extreme cases the cornea, sclera, iris and lens are involved in a common inflammatory process.

When the cornea is involved in syphilis, it is nearly always due to the inherited variety, and is most frequently found in youth. Parenchymatous or interstitial keratitis, is a chronic inflammation of the deeper layers of the cornea, and is usuall due to hereditary syphilis. It occurs usu ally from the sixth to the twentieth yea In the majority of cases we have othe symptoms of hereditary syphilis, such a a protruding frontal bone, concave nos poorly developed upper jaw, etc. The di ease usually extends from the margin t the center of the cornea, until the entir cornea presents a milky or ground-glas appearance, and vision is greatly inte fered with. We may also have keratiti beginning at the center, by appearance o several whitish opaque spots, whic finally coalesce and cause the entire co nea to become opaque. This is usuall followed by great pain, congestion an photophobia. There is always some i volvement of the iris and may have a iridicyclitis, which may cause total blin ness.

The eyelids may be extensively involve in syphilis. They may be the seat o chancres, gummas, papules, pustules, o ulcers, the cicatrix resulting therefro causing ectropion and other deformitie of the lids. No part of the lid is exemp from attacks of sphilitic ulceration. Th palpebral conjunctiva is frequently th seat of mucous patches.

The bones surrounding the orbit ma be involved by osteitis or periostiti which may finally cause necrosis. W may also have an intra-orbital cellulitis resulting in abscess. The lachrymal pa sage may be involved by syphilitic change in nasal and pharyngeal tissues. Thi may cause necrosis and occlusion of th lachrymal duct.

Treatment.—Mercury and the iodide are to be pushed to the point of toleratio in syphilis of the eye, the same as in othe localities. I give mercury in the for of bichloride, and also use mercurial oin ment as inunctions. I usually begin wit a few good doses of calomel, and get th patient's secretions flowing more quickly and then put them on the bichloride. I cases where the iodides are urgently ind cated, I give the iodide of potash. I iritis the first thing is to get the iri thoroughly under the influence of atropi The strength of the solution depends upo the amount of inflammation and adh sions that have taken place. Sometime

one per cent solution every three or four hours is sufficient to dilate the pupil. In others it may require a ten per cent solution, and occasionally I use the pure sulphate of atropin powder, dropping it on the cornea and allowing it to dissolve. The patient must be closely watched and instructed to keep his finger over the lachrymal caruncle, to prevent the atropin from escaping into the nasal cavities and there being absorbed. If these procedures do not succeed in dilating the pupil I then put them on a solution of one grain eserin to three drachms of water, and have it used for three or four days, to contract the pupil, and can usually succeed in breaking up some adhesions. I then follow with atropin again. I use moist heat to the eye by napkins wrung out of hot water. Cold is comforting to some patients, but I am convinced there is more therapeutic value in hot water. Iridectomy is recommended by some to control iritis and prevent its passing into glaucoma, but it is very rarely indicated. Sub-conjunctival injections of bichloride or mercury solution, or of normal salt solution, acts nicely in some cases. Application of leeches to the temple, where there is severe pain, is very serviceable.

The treatment of retinitis and choroiditis is, rest for the eye, and push the mercury and iodides to the point of toleration. The same treatment is indicated for optic nerve vitreous and sclera, except atropin is indicated in scleral troubles.

In keratitis the same general treatment is indicated. In acute stage, atropin, rest, with colored glasses for the eyes, and hot moist applications. Look after general condition of patient by keeping in open air and improving general condition as much as possible. In the chronic stage the cornea should be stimulated to promote absorption of opacities.

The eyelids, when involved, should be treated as ulcers are elsewhere, with antiseptic powder, etc. When the lachrymal duct is involved it should be probed and free drainage secured, while we push the general treatment. Abscess of the orbit should be freely opened and drained.

[Written for the MEDICAL BRIEF.]

The Need of Educating Both the Laity and Profession as to the Surgical Curability of Cancer.

BY J. CLARK STEWART, M. D.,

Professor Principles of Surgery Medical Department, University of Minnesota.
Minneapolis, Minn.

The surgery of malignant disease is handicapped by lay skepticism, often, unfortunately, reinforced by the influence of ignorant or obstinate members of the profession. Let us briefly note what should be believed and taught the laity by all well-meaning and well-informed physicians.

1. That the great majority of malignant tumors are permanently curable by a properly-designed and properly-performed surgical operation, if such an operation can be done early, before dissemination has begun.

2. That the great majority of all tumors occurring after the thirtieth year are malignant, and hence that all such tumors should be considered malignant until proved benign, such benignity being only capable of complete proof by early removal and microscopic study.

3. Accepting the first two propositions, the third becomes inevitable, viz., that every physician upon becoming cognizant of any tumor arising in a patient over thirty years of age, must advise prompt removal and examination of such tumor. It is, of course, understood that many cancers originate before the thirtieth year, and that all suspicious tumors orig inating before this time should receive the same treatment as above.

4. Operations against malignancy must be thorough or they are useless. They should, when possible, remove the tumor, the first connecting lymphnodes, and the tissues between, in one piece without section of the intervening lymph spaces or canals.

Exploratory operations and those for the removal of suspected tumors must be so planned that they can be converted into complete radical operations without serious technical fault.

5. It follows that the operator who removes the early suspicious tumor generally determines, by the character of his

operative work, the fate of the patient, as bad primary work can rarely be remedied at a later radical operation; hence, he should not operate unless prepared and competent to do the required radical operation.

It would seem not unreasonable to hope that the bulk of the profession would subscribe to the spirit, if not the letter of the above, but, unfortunately, every day brings evidence of the contrary. Ignorant men advise delay, urging that they do not believe cancer is ever cured by the knife; and dishonest men do partial operations for a fee, telling their patients they "have given them all the chance there was," while many procrastinate and search after strange gods until their late advice for surgery puts the honest surgeon in the lamentable plight of doing nothing, or merely a palliative operation, which can not help hurting the cause of surgery against malignancy. Is it to be wondered at that the laity distrust surgery in malignant disease, when for one operation properly performed at an early date, with a resultant cure, there are so many late and imperfect operations performed with inevitable relapse and death. Dishonest operating for a fee, and ill-judged operating in charity cases, when no permanent good can be reasonably expected, can not fail to harm the cause of the surgery of malignant disease. Carefully explained palliative operations are only justifiable when considerable temporary benefit will accrue to the patient, because they delay the education of the public, who can not easily appreciate the object of a palliative surgical operation, and count all such operations as failures.

The laity has been educated to consult the surgeon promptly for a pain in the right abdomen, and submits to an early operation in appendicitis or gall-stone disease quite readily, but while these diseases untreated surgically have only a comparatively low mortality, every case of malignant disease means a lingering and horrible death, only preventable by the earliest and most skillful surgical treatment.

I omit consideration of the treatment of malignancy by the X-ray, radium, caustics, etc., and also by the injections of various substances. All of these are only applicable to occasional cases, and, while each may boast some cures, their use probably causes fatal delay in vastly more cases. As X-ray treatment is now so much in vogue, and as it offers such opportunities for disastrous delay, it may be well to review its position in surgery. All small superficial epitheliomata of the face, nose, ears and eyelids can be successfully treated by X-ray, and this is probably here the method of choice, both as to cosmetic and curative results.

In epitheliomata of the lip, tongue, and all other malignant tumors, the concensus of opinion of both X-ray operators and surgeons, is that surgical resources should be exhausted before turning to other methods of treatment. Some remarkable cures of inoperable cases have been reported, but the vast numbers of failures in similar cases can only be guessed at.

Nothing but thorough education of the profession and laity, as to the surgical curability of cancer when seen early, and prompt action, based on such education, can greatly increase the present percentages of cure in this dread disease.

Diseases of the Breast.

BY ALFRED DE ROULET, B. S., M. D.,
Chicago.
Formerly Professor of Surgery and Diseases of Women in the Medical Department of Trinity University.

I. METHODS OF EXAMINATION.

In few diseases are well-trained powers of observation and wide clinical experience of greater value than in the differentiation of the various diseases of the mammary gland, and in no other organ does disease, in its early stages, furnish less data available for positive diagnosis.

Before attempting to discuss pathological conditions, it is well to familiarize ourselves with the varying characteristics of the normal breast. In practice to attain this familiarity, no opportunity to make such examinations should be neglected. Not only does the breast differ greatly in size, shape, consistence, and general appearance in different women,

but in the same woman it presents widely-differing characteristics under varying circumstances and at different periods of life. At no time can the breast be said to have a permanent structure.

In infancy the breast is rudimentary and consists of a group of small, club-shaped, radiating ducts, with somewhat dilated extremities (Fig. 1). These ducts are lined with epithelium, and are surrounded by a connective tissue stroma. Microscopically, the epithelium shows evidence of active proliferation, and the ducts are more or less filled with epithelial debris. Occasionally, swelling and tenderness, with a milk-like discharge from the nipple, the so-called acute mastitis of infants, may be observed, even at this stage of development. As the condition is due to the active proliferation of

FIG. 1. Mammary Gland from Embryo.

the epithelium of the ducts, rather than to an inflammatory process, spontaneous recovery is the rule, although infection and even abscess formation have been observed in such breasts.

Between infancy and puberty both infections and new growths in the breast are exceedingly rare.

At puberty the mammary gland undergoes a marked hypertrophy, the enlargement being attended by considerable pain and tenderness. While there is a great increase in the glandular structures, epithelial-lined acini, arising by a process of budding from the previously existing rudimentary ducts, the virgin breast owes its size principally to deposits of subcutaneous fat, and the development of a delicate, almost transparent, periductal connective tissue. This tissue is peculiar to the breast, and presents a marked contrast to the coarser interstitial connective tissue. (Fig. 2.)

With the advent of pregnancy the character of the breast again changes. There

FIG. 2. Lobule of Mammary Gland showing arrangement of periductal connective tissue.

is a tremendous proliferation of the glandular elements, the acini increase enormously, while the stroma becomes attenuated, and the periductal connective tissue no longer predominates. In Fig. 3 is shown an enlarged model of the acini and ducts of a single lobule. During this development the breast is painful, and on palpation the glandular structures may be felt as thick, cord-like masses. The areola changes from the delicate pink of the virgin to a color ranging from a light brown in a pronounced blonde, to a brownish black in a brunette. With the cessation of lactation this color fades some-

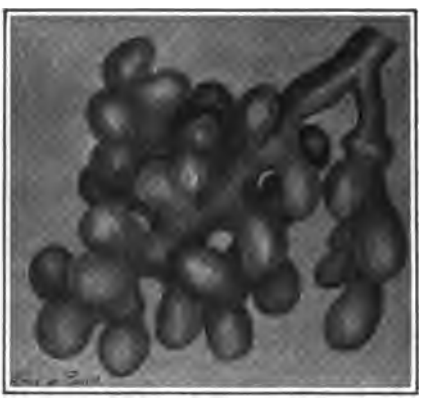

FIG. 3. Model of Lobule in Lactescent Breast. (X 200.)

what, but the original pink is never fully restored.

When lactation ceases, the breast undergoes certain retrograde changes, the

glandular tissues atrophy, many of the epithelial debris, or obliterated by the connective tissue becomes relaxed and flabby. The gland now remains quiescent until the recurrence of pregnancy again calls it into functional activity, or the advent of the menopause is followed by senile atrophy.

In the senile breast the glandular elements undergo a progressive atrophy until a few strings of connective tissue, radiating from the nipple, and a few shreds of the fibrous stroma, imbeded in the adipose tissue, is all that remains of a once active gland. In some particularly well-nourished women, even those well-advanced in years, the breast may show no apparent diminution as a result of these changes, the atrophied tissues being replaced with fat. During this stage of decline the ducts become clogged with

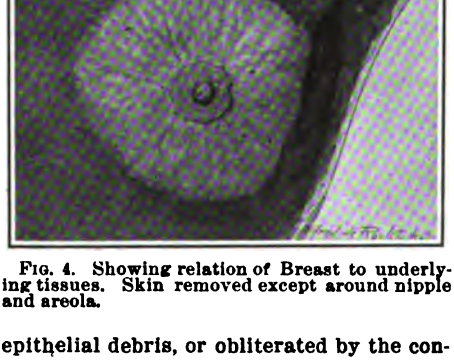

FIG. 4. Showing relation of Breast to underlying tissues. Skin removed except around nipple and areola.

epithelial debris, or obliterated by the contracting interstitial tissues. As a result, small, hard nodules develope, which, on section, are found to be small cysts, containing a slightly discolored fluid. These small cysts are present in practically all breasts at some period of their decline, and should be regarded as incidental to this process, and as devoid of pathological significance.

In the adult virgin the breast should be roughly hemispherical in shape, and firm and elastic to the touch. It should extend from the third rib downward to the sixth or seventh, and from the border of the sternum to the anterior axillary line (Fig. 4). The degree of fullness or projection depends on the amount of adipose and periductal connective tissue present. A firm, projecting breast is characteristic of the virgin, while after lactation the breast is more or less pendulous. While the outline of the gland is commonly described as circular, it is usually somewhat triangular, owing to the presence of three more or less pronounced extensions, one projecting toward the sternum, one toward the upper, and one toward the lower portion of the axillary space. The axillary process, not infrequently, curves in behind the lower border of the pectoral muscles, and occasionally, it is unintentionally left behind in amputations of the breast.

Bearing in mind the anatomical and physiological peculiarities of the breast, a knowledge of the comparative frequency with which certain conditions appear, together with the time of life and previous mammary history most favorable for their development, is often of great value in making a diagnosis. Unfortunately, in many cases the diagnostic indications are very indefinite. The objective signs are vague, and often so masked as to be almost impossible of detection, while other signs of great importance do not appear until late in the disease. The history, as given by the family, is often imperfect, if not actually misleading. For example, the patient fears she has a cancer, but dreads having her fears confirmed, and for this reason gives an entirely mendacious account of the development of her trouble, denying symptoms which she has, and strenuously asserting others which have no existence, save in her imagination. In such cases considerable tact and judgment is necessary to arrive at the facts. In all cases, however, every effort should be made to obtain a complete and correct history of the case, and every point which could, in any way, have the slightest bearing on the condition should be carefully investigated. In this way many sources of error may be avoided.

As to the physical examination of the patient, a proper technique is of considerable importance. The patient should be seated in an ordinary chair, her arms hanging loosely at her sides, and her entire chest and shoulders bare. It is absolutely impossible to make a satisfactory examination with the patient sitting bolt upright on the edge of her chair, her

arms rigid, and three buttons in the front of her dress unfastened. Should it be considered advisable to examine the patient in the recumbent position, she should be placed flat on her back, with

FIG. 5. Correct Method of Palpating Breast.

her head and shoulders slightly raised, and her arms resting easily at her sides. The patient having been properly prepared, both breasts are inspected, any difference in size, color, or contour being noted, as well as any alteration in the character of the skin, as dimpling or induration. The appearance and position of the nipples should be noted. In cancer the nipple of the affected breast is often not only retracted, but is drawn toward the new growth. The examiner should next place the palm of his hand over the breast and gently press or roll it against the chest wall (Fig. 5), when any alteration or irregularity of consistence in the tissues will easily be detected. If no tumor is felt in this manner, it is safe to assume that there is none present. On the contrary, when the tissues are pinched up between the thumb and fingers (Fig. 6) mistakes are easily and frequently made, probably the most common being that of mistaking normal glandular tissue for a new growth. Should a tumor be found, it should be examined with regard to size, character, consistence, character of outline, degree of mobility, the presence or absence of tenderness or pain, and the condition of the axillary and cervical lymphatics. If there is any discharge from the nipple its character should be noted.

By moving the hand lightly to and fro, laterally, over the breast, the presence of adhesions between the tumor and the skin may be determined, while with deeper pressure, the pectorals being held rigid, the presence or absence of adhesions to the pectoral muscles may be detected. With the tips of the forefingers the relative hardness of the tumor, as well as the presence of fluctuation, may be ascertained. In examining the axilla it is necessary to examine also the unaffected side for purposes of comparison, as enlarged lymphatics are not uncommon, and their enlargement on the affected side may have no connection with the condition of the breast. While the whole axilla should be explored, enlarged

FIG. 6. Incorrect Method of Palpating Breast.

glands are most frequently found along the course of the axillary vein (Fig. 7). The hollow above the clavicle and along the posterior border of the sterno-mastoid should be carefully examined. It would

hardly seem necessary to insist upon the necessity for extreme care and gentleness in all examinations of the breast. In inflammatory conditions rough handling causes the patient much unnecessary pain without adding in the slightest degree to the value of the examination, while in malignant troubles unnecessary manipulation and handling are undoubtedly important factors in promoting a rapid spread of the disease, by forcing cancer cells along the lymph channels.

A single nodule in the breast may be cancer, or it may not. Multiple swellings

FIG. 7. Showing General Course of Lymphatics.

found in both breasts are probably due to chronic cystic disease, while multiple swellings, limited to one breast, may be cystic in origin, or may be due to the presence of fibroadenomata.

As a rule, cancer appears most frequently in the upper outer quadrant of the breast, sarcoma in the upper inner quadrant or immediately below the nipple, while a fibroadenoma is found at the periphery, rather than in the central part of the breast, and is superficial, rather than deep seated, and although both breasts are rarely involved simultaneously, several tumors of this variety may develop in the same breast.

As regards consistence, a hard, inelastic tumor is characteristic of carcinoma; a sarcoma is often rather soft, while the various cysts and fibroadenomata are firm and elastic, their feel resembling somewhat that of a slightly-wilted potato. Elasticity or fluctuation in a tumor is sufficient to warrant a diagnosis of cyst, but inability to elicit either does not absolutely bar this diagnosis.

While the borders of a benign tumor are, as a rule, clearly outlined, the outlines of a swelling, due to chronic abscess, tuberculosis, or cancer, are vague and indistinct, it being impossible to distinguish the line where abnormal tissue stops and normal tissue begins. While a sarcoma infiltrates the surrounding tissues, the infiltration is rarely perceptible to ordinary palpation. The presence of pain and tenderness is often a symptom of very uncertain value. As a rule, chronic inflammations are accompanied by a certain degree of tenderness, and may be actually painful; and, as a rule, cancer in its early stages, is unaccompanied by either marked pain or tenderness. Unfortunately, the idea that cancer is always attended with agonizing pain is so firmly rooted in the minds of the laity that it is often difficult to convince them that a cancer may develop without causing any appreciable suffering. Occasionally, patients with mammary cancer notice a slight stinging pain, which comes and goes, lasting but a few moments, and disappearing to return again after an interval varying from a few hours to several days. The stinging is rarely severe, but when present its peculiar quality renders it almost pathognomonic of cancer. Enlargements of the axillary lymphatics may be due to inflammatory conditions or to cancer, but the absence of lymphatic involvement does not preclude the possibility of cancer.

If, by gentle manipulation of the tumor, a clear, serous fluid can be made to flow from the nipple, in all probability the tumor is a simple cyst; if the serous fluid is slightly blood tinged or brownish, a tentative diagnosis of intracystic papilloma may be made; while if the discharge consists wholly or in great part of pure blood, it is very suggestive of cancer.

[Written for the MEDICAL BRIEF.]

Collinsonia Canadensis.

BY FINLEY ELLINGWOOD, M. D.,
Editor "Ellingwood's Therapeutist."
Chicago, Ill.

This common herb, known as stone root, possesses many valuable properties. It must be studied with reference to its specific action. Its general influence is that of a mild, gastrointestinal tonic, and in the exercise of this influence it is superseded by a large number of better-known remedies.

The specific symptomatology to which I would direct attention is that of a constriction and heat, with weight—heaviness—in the rectum. A sensation of fullness or the sensation as of a foreign body in the rectum, especially if accompanied with stricture or cutting pains. It is also indicated where there is deficient secretion from imperfect capillary circulation, and especially where there is passive congestion, with blueness or discoloration of the membranes.

So direct is its influence upon the walls of the veins and upon the venous capillaries that I was led, twenty years ago, to prescribe the remedy for varicosis in any locality. I have administered it where there was persistent varicosity in the limbs, and if given in the early stages it is a very serviceable remedy, especially if hamamelis be applied externally. I have treated varicocele with this remedy when the condition in young men was just starting, and have succeeded in checking its development, and causing the disappearance of the enlargement, in a few cases.

I recently prescribed this remedy in a case of extreme acute varicose veins within the vagina, in a woman five months' pregnant, and succeeded in removing the condition very satisfactorily. In this case I used the remedy in conjunction with douches of equal parts of collinsonia and distilled extract of witch-hazel, diluted.

For nearly thirty years I have used this remedy for piles. Although I have got into the habit of combining the remedy with hamemelis, I feel confidence in the influence of this agent, because the results obtained are impossible with hamamelis alone. In cases of piles of recent occurrence, I combine a heavy fluid extract of the two remedies in equal parts. Of this I give twenty to thirty drops in water every two or three hours. At the same time the piles should be bathed externally with distilled extract of witch-hazel, full strength. In chronic cases, I at first use as an external application, a solution of persulphate of iron, and I have then bathed them with the combined heavy fluid extracts of full strength, a small quantity of which should be injected into the rectum after each bowel movement.

The remedy is valuable in subacute proctitis, muco-enteritis, and in some forms of dysentery. It is especially valuable in subacute dysentery, where there is marked atonicity. When it has been necessary from fistula, or from rectal ulcers and piles, to perform an operation upon the rectum, this remedy should be given in reasonable doses, both before and after the operation, and should be continued for two or three days. It will do away with a large portion of the distress in the rectum, and will conduce materially to the healing of the parts.

In conjunction with gelsemium and aconite, as indicated, it will be found a very serviceable remedy in acute cystitis. This is due to its influence upon the capillary circulation within the pelvis.

There are other conditions for which this remedy has been recommended, outside the suggestions pointed out by its specific symptomatology. There are certain general atonic conditions where it acts admirably with hydrastin in chronic stomach troubles, and where there is functional heart disorder, such as palpitation or irregularity; it may be combined with cactus, and will produce satisfactory results. Probably the most severe case of epilepsy I have ever seen, was kept in check, and the spasms warded off for eighteen months by the use of collinsonia in tablespoonful doses every two or three hours. I have not found any other physician who has used this remedy for epilepsy, and I am anxious to receive reports from those who have.

Conditions, however, in which the best results from the agent are obtained, are

pain in the rectum, as mentioned, especially that due to causes not readily determined.

The agent has been used among our physicians for many years for chronic pharyngitis, and while I believe it will be found valuable in many cases of this troublesome disease, I have not obtained from its use the best of results.

In chronic gastritis, with extreme atonicity, it should be given with hydrastis and capsicum, and if continued for a protracted period the results will be highly satisfactory.

[Written for the MEDICAL BRIEF.]

Some Thoughts Upon the Therapy of Pneumonia.

BY WILLIAM HENRY CHRISTIE, M. D.,
Professor of Materia Medica and Therapeutics in the University of Nebraska.
Omaha, Neb.

The treatment of pneumonia must depend altogether upon the history of the case, upon the patient himself, his habits of life, environment, age, etc., and there is no such thing as a specific for this disease. In certain forms of pneumonia, such as the croupous variety, where the cough is harsh and the fever high, these symptoms can be ameliorated by various forms of medication, but for pneumonia proper we have no specific. And this is not surprising when we consider the variety of forms assumed by this disease. Almost every case differs from the previous one in some respects, and features are important and must be studied and treated rationally. As the history of almost each individual case varies so much, the treatment must vary to meet the requirements. Our therapy must meet the conditions as they arise. For instance, if our patient shows a tendency toward feeble circulation, traceable to the cardiac area, that condition calls for strychnine, and it had better be commenced early than late, the dose depending largely upon the patient's history, whether he has consumed much alcohol, or otherwise.

In patients who have contracted specific disease in early life, and neglected its treatment, this fact will affect the character of the pneumonia. The disease will be of the type peculiar to this history, and these cases must be by the use of iodides, and very often by mercury.

In cases beginning with la grippe, the pneumonia is likely to be of the catarrhal type, and again, the treatment under these circumstances will be different than in croupous forms of the disease. In the latter cases expectoration should be kept up, and in prescribing this fact must be remembered. A good, copious expectoration must be kept up, and, if it ceases, you are liable to have on your hands a case complicated by bronchitis, which complication becomes even more serious than the pneumonia proper. I know of nothing better to meet these complications than chloride of ammonia, very cautiously administered. The tendency will be to relieve the peculiar barking cough, which is usually very distressing, but by preventing this cough we interfere with nature in her effort to clear the bronchial tubes.

In cases where there is much pain in the chest, taking on the form of pleuropneumonia, with pleurisy as a complication, the treatment can be very nicely met by the local application of gaultheria. The oil of gaultheria applied to the chest on a linen layer, which is, in turn, covered with oiled-silk or rubber protective; then a flannel, warmed, is applied over all. The heat of the body will cause the oil to be absorbed. If a four-ply layer of linen be used it will entirely absorb the oil, and no benefit will be derived, but by using a single layer of linen, as above described, the oil is easily and quickly introduced through the skin. The method of doing this is a matter of importance, therefore. At the same time, the salicylates can be administered internally, or if the pneumonia be complicated with pleurisy, the gaultheria may be taken internally in doses of from ten to fifteen or twenty drops in a capsule. Where much pain is present, this treatment will be found to be particularly gratifying.

Where there is a hyperemic of the lungs, due to congestion and dryness of the skin in mild cases of pneumonia, the old-fashioned preparation of ammonia acetat and spirits of niter, the former one-third grain dosage and one-quarter drachm

of the niter for an adult, keeping the patient warm, will produce a diaphoresis, and draw the blood to the surface and relieve the engorgement of the air passages, relieving the cough in a satisfactory manner.

The treatment of pneumonia seems to move in cycles, perhaps because we also move in cycles, and are likely to fall into the trend of them. Our fathers knew a great deal about some of these things, by their observations and through their clinical experience. One measure which they used in the treatment of pneumonia, that of producing counter-irritation to relieve the congestion and consequent exudation, had its reward. It does now. Care must be taken, however, not to use stimulation or counter-irritation until the patient has arrived at the third stage. In this, as in the last measure recommended, the time and manner of doing is of more, or as much, importance as the therapeutic measure itself.

Another treatment employed by our fathers in medicine was the use of the lancet. Once in a while acute cases of pneumonia to-day, where there is marked engorgement and embarrassed respiration, can be benefited by the abstraction of blood. Aconite is also useful in this connection, when there is great congestion of the blood vessels of the lungs. By withdrawing the blood from the lungs and carrying it to the stomach, a marked depletion is produced by the aconite. This, too, requires a knowledge of the physiological effect of this drug, when to use, how far to push it, to get the desired result, etc.

In sthenic cases in malarial districts, along the course of our rivers, quinine has been used in pneumonia, in large doses. I have used it in ten, fifteen, and twenty-grain doses, until it produced the marked physiological effect. I have seen this treatment relieve congestion and pain very quickly. In one case, where this treatment had been carried out to the letter, the pain and distress continued, but the quinine brought about phenomenal results in changing the character of the fever.

As stated in the beginning of this article, there is so much in therapy of pneumonia dependent upon the phases of the disease, that the only rational course is to get the history of the case, and treat it on that basis.

[Written for the MEDICAL BRIEF.]

Relief of Insane Conditions by Surgical Procedure.

BY ARTHUR McGUGAN, B. SC., M. D.,
Professor of Neurology and Psychiatry in the University of Colorado.
Denver, Colo.

It has been established that many abnormal conditions of the mind and nervous system can be relieved by the correction of anatomic defects, and the relief of reflex irritation by surgical means. During the early period of my profession this surgical interference with the pelvic viscera was carried to a ridiculous extreme, bringing well-marked censure on this form of treatment applied to insanity, and it is only recently that the status of operative procedure has been even approximately established. In meetings of medical societies devoted to discussions of a general character, very little is heard, even yet, of the work being done along this line, and only in those organizations concerned particularly with insanity will be found reports and records of progress. Even here, there is a lack of unanimity of opinion, the more conservative doubting the real value of these procedures, while some of the younger and more radical members of the profession are inclined to make claims not quite justified by results.

I have performed and reported upward of fifty operations for the relief of insanity and epilepsy, and am presenting the appended report as one characterized by some features of particularly instructive value.

I was called to a neighboring town July 10, 1904, to see Mrs. W. C. J., reported to be violently insane. I found her manacled, hand and foot, to a bed in the little hospital, under the care of two nurses and the attending physician. The preliminary examination and history revealed the following:

Patient twenty-three years old, married nine months; miscarriage two months before. Previous health good.

Family History.—No insanity, tuberculosis, epilepsy, inebriety, or any other condition predisposing to defective organization.

Patient's mother was present and closely observed.

Patient's History.—Delivery at full term, naturally. Ordinary diseases of childhood; progress at school rather better than the ordinary. Graduated from an Eastern college one year ago. Is active, athletic, cheerful disposition, and happy in domestic relations.

Status Presens.—At the initial visit complete examination was impossible, but at this time, and on subsequent visits the additional facts were obtained.

Digestion.—Lips, teeth and tongue covered with sordes, due to lack of food and water ingestion. Tongue bright red at the edges and heavily coated. Teeth and jaws normal. No history of indigestion; occasional transient constipation. Body weight reduced from ten to fifteen pounds. Circulatory and respiratory system normal.

Genito-urinary System.—External parts normal. Uterus completely retroverted; fundus considerably enlarged; slight semi-purulent discharge; both ovaries prolapsed. Some external tenderness over the fundus and the right ovary.

Nervous System.—Deep reflexes increased; pupils slightly widened and active. Superficial and organic reflexes normal. No paralysis, anesthesia or paresthesia.

Persistent headache, principally at the vertex. Persistent insomnia for the past two weeks.

The mental picture was in the formative stage, varying from day to day; its analysis, therefore, can not be made exact, but in general the following errors predominated:

Intellectual Processes.—Sensation travels rapidly, usually painful; perceptions acute, but erroneous, especially auditory, resulting in occasional hallucinations of this sensation. Memory blurred by the increased flight of ideas. Ideation very rapid and incoherent, at times. At other times very slight, even to dullness. Reasoning and judgment much impaired and marked by painful delusion of a persecutory type and rapidly-changing errors in identity. For instance: On one day the nurse was thought to be the mother, on another day a friend, and at some other time a stranger whom she had never seen before.

Mental Processes.—General tone of feeling, both physical and mental, was usually much depressed. Disorientation, both as to person and place, was so complete that beyond the condition of depression and the attitude resulting from it, that no correct observation of the patient's attitude towards herself and environment could be made.

This blurring of mental processes is always more or less complete, depending upon the patient's capacity for the expression of different states of feeling.

Motor Processes.—All involuntary processes are increased, due to the lack of inhibitory control. Of the voluntary processes it is noted that ordinary acts, in general, were of the impulsive variety, not controlled and not modified by the ordinary normal restraining impulse. Thus, general motor restlessness led her to destructiveness and acts of violence against her attendants. These and all her acts were, in some degree, purposeless. For instance, she did not know why she wished to destroy this particular article, or injure that particular person, nor why, on occasion, she felt like harming herself.

The case was diagnosed as one of the active exhaustive psychoses, according to the classification of Kræpelin.

Prognosis favorable. It was advised that the patient be removed to an institution for the insane, and that as soon as her motor restlessness could be controlled that the condition of the uterus and the ovaries be treated surgically. This advice was accepted by the relatives, and the patient was removed to a private hospital in Denver. She was placed in charge of a nurse experienced in the care of the insane, and treatment was directed, first, to the relief of the insomnia and restlessness. It consisted in the alternating tepid pack and warm bath, the pack applied one-half hour daily, the bath for two hours. The headache was relieved by the persistent use of the ice cap. By the end of the first week she was sleeping naturally, and the restlessness had disappeared. Improvement in all respects

was noted, excepting her delusions, which were becoming more fixed, showing a tendency to systematic arrangement. On August 10, 1904, she was removed to a general hospital for the purpose of curettage and ventro-suspension. Convalescence from the operation was established, after the ordinary interval; that is, about two weeks. Complete restoration of the mental faculties occurred a few days before, or, in the second week following operation. In a few days more she returned to her home, and, with the exception of a slight depressed spell in the second year following operation, and due to extreme worry over financial matters, she has been in perfect health. She presented herself yesterday, weighing twenty pounds heavier than at the time of operation, expressing herself as feeling perfectly well in all her mental faculties, and having been so quite constantly since the time she was under my observation.

This case differs from all others that I have reported previously, in the fact that the patient is, apparently, of normal mental and physical development. By this I mean that physically she presented no stigmata of degeneration of cranial, facial, body, mental, or moral type. That her previous history shows no record of the peculiar perks and foibles always marking the previous life of the ordinary case of insanity, and that her family history presents no condition carrying predisposition to mental deterioration in the descendants.

My experience with the insane, based upon accurate report and tabulation of cases, leads me to believe that a high percentage (about ninety-five) is marked by some or all of the defects above referred to. In my previous observation of insane persons operated on for relief of insanity the cases were all of this defective type. The operations done for their relief were done upon the assumption, first, that all anatomic defects in the insane should be corrected, and all reflex irritation be removed, as these conditions are all considered barriers to progress towards mental restoration. In the second place, that it is known and admitted that surgical intervention of any kind, even without structural necessity, frequently results in mental cure. In such cases it is not always held that the anatomic defect is the cause of the psychoses. But both the defect and the psychoses arise from the same cause, that is, defective organism. It is held, though, that if the anatomic defect can be corrected, the patient's vegetative and general functions will be improved, to a greater or less extent, thus facilitating recovery. In this case the basis for surgical intervention is one entirely apart from these considerations. The anatomical development, in all respects, was perfect, and the condition corrected was considered one of recent pathological acquisition. It was confidently expected that the relief of this condition would be followed by prompt mental improvement, in which, as the report shows, we were not disappointed.

I regard this case as one very similar, in its etiology, to the cases familiarly known as puerperal insanity, and which are now classified among the exhaustive psychoses. The influences bearing upon the nervous system and producing mental unbalancement, were psychic in character, due to the fear and distress of mind incident to an abruptly-terminated pregnancy, and the material influence consisted in the abnormal position of the uterus and adnexa, as well as the possible infection from retained products.

Majestic Building.

[Written for the MEDICAL BRIEF.]

General Considerations of Stomach.

BY CHARLES NOOTNAGEL, M. D.,

Professor of Clinical Medicine and Physical Diagnosis in the University of Minnesota. Minneapolis, Minn.

I have chosen the stomach as my theme, not because of its interest to all, but because of the position which its diseases do already or will soon occupy in the field of medicine. We are beings who love extremes, and it was with the "humors of the blood" a century ago (they were regarded as the cause of nearly every disease under the sun), so will it probably be with the abnormal functional and anatomical conditions of the stomach; this will obtain, at least, for the gastric enthusiast—specialist, I meant to say. During the last two decades of this

century, however, our knowledge of the diseases of the alimentary tract in general, and of the stomach in particular, has become so much broadened and enriched by facts gleaned by investigators and observers all over the world that we can not be blind to the fact indicated thereby, *i. e.*, the importance accorded to diseases of the stomach by the masters of our profession. And this is as it should be, judging from a physiological point of view. Everything ingested, either for nourishment or for the purpose of tickling our perverted palates, must, of necessity, enter the stomach and there be prepared for absorption or further elaboration in the intestines, or be discarded as useless or worse than useless, for many of the condiments and stimulants stand in direct causal relation to certain gastric diseases.

Again, the basis for gastric diseases is often laid at or soon after the birth of many children. To illustrate this point, allow me to call your attention to the many injurious decoctions poured into the newborn's delicate stomach by well-meaning but misguided persons assisting about the lying-in chamber, and this practice of giving unsuitable food and drinks is continued in innumerable instances during childhood, and later. This pernicious practice not only lays the foundation for the development of various gastric diseases alone, but paves the way for a hundred and one other diseases to gain foothold in our bodies by lowering the general vitality. This opens a field for our serious consideration almost too vast for our comprehension, with our present knowledge of the relations which one disease bears to the origin of another. To enter more fully into this part of the subject would carry us far beyond the limited scope of this paper, but I wish merely to intimate possibilities.

Judging from the very general irrational manner of feeding the young in our land of plenty, the foreigner is justified in calling us the "dyspeptic nation," and in order to treat, and also to prevent as much as possible, gastric diseases, we ought, by rights, to commence at the very beginning, *i. e.*, immediately after birth of the child, and then continue the good work by teaching it the principles of correct eating, so that it may, after attaining manhood or womanhood, as the case may be, preserve its normal digestive energy, and thus avoid endless and useless suffering. The old adage, "an ounce of prevention is worth a pound of cure," is as applicable in this instance as in any other.

But what concerns us more directly, as medical men, is the diagnosis and cure of gastric diseases.

Since the advent and intelligent use of the stomach tube, diagnosis of gastric diseases has stood in the front rank of progress in medical science. In fact, we have since then learned so much in regard to gastric diseases that the number of cures effected have materially increased during the last few years. The progressive physician is no longer at the mercy of empiricism, inasmuch as he may, by the aid of the stomach tube and chemical analysis, arrive at definite conclusions and direct his treatment with precision.

The following cases may serve to illustrate this point:

Mrs. N., thirty-eight years old, farmer's wife, complained of dyspeptic symptoms for the past twelve years; was treated for various gastric and other diseases, but without success. She was referred to me by a colleague, under whose care she had been for some time. *Status presens:* Looks very sallow, very much emaciated, lost forty pounds during the past two years; complains of anorexia, dizziness, headache, bloating after eating, especially after the ingestion of fats and carbohydrates; constipation; vomiting, especially in the morning, the vomitus containing a great deal of mucus; also feels nauseated after eating; urine scanty, but free from sugar, albumen and casts; menstruation regular, but scanty; sleeps poorly, tongue heavily coated, and the papillæ at its base very prominent.

Physical examination (about one hour after dinner): Gastric region and entire abdomen distended and tympanitic. By careful percussion the stomach, apparently reaches one and one-half to two inches below the umbilicus. This was verified, both by the inflation with gas and also by pouring in water through the stomach tube, and marking the lower and upper limit of dullness, then syphoning

out the water and noting the change in these limits.

Chemical examination of stomach contents an hour after the ingestion of the usual test breakfast; obtained stomach contents with ease by means of the stomach tube. The stomach contents contained much of the ingested bread and only four-hundredths of one per cent of free and combined hydrochloric acid. The test with congo paper, and also that with tropaolin, gave negative results. Uffelmann's test for lactic acid showed only a trace. There was much mucus present.

Diagnosis.—Chronic gastritis, accompanied by gastrectasia and decreased secretion of hydrochloric acid. Judging from the large amount of mucus present, no atrophic condition of the gastric mucous membrane existed.

Treatment.—First and foremost, the diet was carefully regulated and everything was well masticated and slowly eaten. At first the diet consisted entirely of animal food, such as scraped beef, oysters and white meats; also chopped raw smoked ham was eaten with a great deal of relish, and with no apparent bad effects. After a few days, well-toasted bread was allowed, and from then on the quantity and variety of food was increased.

Next in importance was the nightly lavage of the stomach, at least four hours after eating the last meal. At first I used sodium bicarbonate in the water for lavage; afterwards, sodium salicylate. The diet was as dry as possible, and to quench the thirst a wet sheet was wrapped about the abdomen during the night, and if thirst became annoying I gave an enema of cold water, repeated as often as required. This always quenched the thirst admirably. Schroeth was the first to institute this dry diet for the cure of gastrectasia, and the treatment is, therefore, known as Schroeth's dry diet cure.

Marked improvement was noticeable from the first day of this treatment; all disagreeable symptoms disappeared within six weeks, and patient left for home at the end of this time. On inflation with gas the stomach now extended only down to the umbilicus; this was verified by the introduction of water, noting resulting area of dullness, and syphoning out the water, and then noting change in the dull area. No medicinal treatment was used in this case.

After patient had been home for some time she became lax in observing the strict dietary rules, and soon some of her former symptoms reappeared; this frightened her so that she has been careful to follow my instructions to the letter ever since. Just prior to her departure, the contents of the stomach were examined quantitatively for free and combined hydrochloric acid, which had gradually increased in amount ever since her stomach was washed out regularly, and was found to be 0.14 per cent, which, as you know, is slightly below the normal.

This case is very instructive for several reasons. First, the gastrectasia was entirely due to chronic gastritis. Second, the abundance of mucus excluded an atrophic condition of the gastric mucous membrane. Third, the marked improvement following a more suitable diet and gastric lavage without the use of any medicinal treatment whatever. Fourth, the marked shrinkage of the dilated stomach occurring after the employment of dry and suitable diet for some time.

I have several times seen dry diet mentioned for the treatment of gastrectasia, but never in the manner in which I employ it. With the older method of dry diet, *i. e.*, withholding water or fluid of any kind almost altogether, or allowing it only in the form of a wet pack during the night, I think the fluid introduced is sufficient for the body's requirements, and, in consequence, patients do not improve as rapidly and do as well under this treatment as where water is abundantly supplied by rectal injections.

I could cite some other cases where equally good results were obtained by dry diet and rectal injections of water in cases of gastrectasia due to chronic gastritis, but I wish to reserve my space for other considerations in this connection.

By the way, Liebermeister mentions, casually, that nutrient enemata have, besides supplying food, the additional advantage of supplying much-needed water to the patient while undergoing the dry diet cure.

Strict rules must be laid down by the physician, and be implicitly followed by

the patient, otherwise no good results can be obtained.

The following is a case in point: Mrs. M., twenty-nine years old, has complained of dyspeptic symptoms ever since puberty. On physical examination I found lower boundary of stomach extended two and one-half inches below umbilicus. Chemical examination of stomach contents an hour after test breakfast showed twenty-five one-hundredths of one per cent of combined and free hydrochloric acid; also much mucus and nearly the entire test breakfast was removed by the stomach tube.

Diagnosis.—Chronic gastritis, accompanied by gastrectasia and deficient motor power of the stomach.

Treatment.—Carefully selected dry diet, with gastric lavage four hours after patient's last meal in the evening. Sodium bicarbonate was used in the water for lavage, also rectal injections of water were ordered to be taken whenever thirst began to be annoying. During two weeks of rigid observance of these regulations most of the disagreeable symptoms ameliorated, and the patient became tired of the restrictions placed upon her, and indulged in a "good square meal," ending up with ice cream, cake, etc. The result was as might be expected, a complete return of her former symptoms with a vengeance, and now the patient is willing to obey orders.

One remarkable feature of this case is the fact that after washing out the stomach, four hours after the patient's last meal, the water will, finally, return perfectly clear; but if the patient retches, fluid, loaded with food remnants, reappears. This may either be due to a sacculated condition of the stomach, which in this case I can not determine by physical examination, or to an insufficiency of the pylorus. In addition to the above treatment, I now apply faradization to patient's stomach four hours after last light meal, by placing an electrode over gastric region and introducing the other into the stomach through a stomach tube, previously having introduced into the stomach a considerable quantity of water. The internal electrode I have constructed out of two twisted, thin copper wires, armed with a small pledget of cotton at the lower end. The wires are first introduced into the stomach tube and forced out through lower fenestrum, then attached to pledget of cotton, which, in turn, is packed tightly into lower closed end of stomach tube, and the electrode is ready for use. The electrical connection is established by the cotton submerged in the water previously introduced. After ten minutes' faradization, with frequent interruptions, I proceed to wash out the stomach through my improvised internal electrode, and, apparently, the stomach was on each occasion almost empty, since but very little food was brought up by the wash water, and the water syphoned out was but slightly, if any, in excess of the amount introduced for the lavage. The final issue of this case must be reserved for some future occasion, since not time enough has yet elapsed since the commencement of the treatment of this case to warrant me in judging of the final result.

The most prolific cause of gastrectasia is pyloric stenosis, and the second in casual importance is the habit of gormandizing; the latter produces chronic gastritis and this, in turn, gastrectasia. The many other causes need not be mentioned here.

By suitable and dry diet, we have seen by the above what brilliant results can be obtained. Of course, the treatment must be instituted before an atrophic condition of the gastric mucous membrane has developed. Now, the question arises as to which of the existing conditions, the chronic gastritis or the gastrectasia, is the more instrumental in producing the phenomena of disease. In my humble opinion, the former is almost wholly responsible, because we see in cases of megalogastria no evil results following from the great capacity of the stomach, so long as its secretory and motor functions proceed normally; again, in the case of savages, who, during periods of plenty, habitually overload their stomachs, and, in consequence, acquire permanent gastrectasia, we find none of the symptoms developed commonly attributed to gastrectasia. Of course, I do not wish to be understood as maintaining that gastrectasia does not add certain symptoms to an already existing chronic gastritis, but I do

wish to be understood as maintaining that chronic gastritis is the prime and most important condition demanding our serious attention and treatment. As long as we can maintain normal gastric secretory and motor functions, no evil results from simple gastrectasia, but just as soon as either of these become insufficient abnormal sensations and symptoms of gastric disease will supervene.

As to the causative action of micro-organisms in the production of gastric diseases, my limited observation leads me to believe that they are the result of gastric disease rather than the cause.

After this digression, let us return to the means at our command for arriving at a definite diagnosis and directing our treatment with precision. First of all, we must, by physical examination, determine the size and location of the stomach. This can, sometimes, be accomplished by simple percussion, but this alone is not reliable, and must be verified by one of the various other methods at our command; for instance, by allowing the patient to drink a glass of ice water and, after the lapse of a few minutes, feel for the lower boundary of the cold area produced upon the abdomen, or by distending the stomach with carbonic acid gas, produced by the introduction, first, of a solution of tartaric acid, and followed by one of bicarbonate of soda; or, better still, by filling the stomach with water through a stomach tube, and then determining the lower boundary of dullness by percussion, then syphoning out the water and noting the change on percussion. By these procedures the size, conformation and position of the stomach can be accurately ascertained.

By administering iodide of potassium in gelatin capsules and, subsequently, testing for its appearance in the saliva, we can determine the absorptive power of the stomach.

We possess two methods for determining the motor power of the stomach. We may either administer salol and, subsequently, test the urine for salicylic acid, and the time consumed before the latter becomes demonstrable will give us a fair index of the motor power of the stomach; or we may withdraw the stomach contents through a stomach tube, at a certain time after the ingestion of a test meal. The latter method is probably the more accurate and convenient, because it gives us an insight into the quantity of food still remaining in the stomach, and at the same time also furnishes us a sample of the stomach contents for chemical examination. This sample we test for free hydrochloric acid; then the amount of free and combined hydrochloric acid must be determined. The most accurate and convenient means at our command for doing this is the incineration method, so prominently brought before the profession by Professor Leube. Although this requires an elaborate chemical outfit and some knowledge of quantitative analysis, still the results obtained will amply repay one for the additional expense and labor involved. I employ this method exclusively, and can vouch for its accuracy, not alone from my personal experience, but from having seen comparative quantitative analyses of stomach contents made while working in the laboratories at Wurzburg, under Professor Leube's supervision, and at Berlin, under the direction of Professor Gerhardt.

Then we must test for the products of proteid digestion, also for lactic, butyric, and acetic acid.

We should also subject the stomach contents to a careful microscopical examination.

All these procedures aid us in arriving at definite conclusions in regard to the conditions existing in the stomach, and at the same time guide us in selecting methods of treatment with more precision. For instance, the continued absence of hydrochloric acid indicates gastric carcinoma, if supported by other symptoms indicating this malady. Constant hyperacidity, in connection with certain other symptoms, indicates gastric ulcer. The presence of lactic, butyric and acetic acid, and numerous micro-organisms, points to fermentative changes going on in the stomach, and in such cases the diet demands careful regulation and gastric lavage should be employed. Large quantities of mucus in the stomach point to a catarrhal condition, etc., etc.

In conclusion, I wish to state that it was not my intention, in this brief paper, to treat exhaustively any one abnormal

gastric condition, but, rather, to call attention to some of the more modern methods of diagnosis upon which to base definite conclusions and rational treatment.

Andrus Building.

[Written for the MEDICAL BRIEF.]

Post-Operative Cystitis; Its Prophylaxis and Treatment.

BY JACOB BLOCK, M. D.,

Professor of Genito-Urinary Surgery in the Medical Department of the University of Kansas. Kansas City, Mo.

The term indicated in the title is employed as a convenient means to diagnosticate catheter infections, where this instrument is employed to relieve retension following operations. It is not limited to genito-urinary operations, but includes almost any operation in the field of genito-urinary surgery, and is of consequence to the obstetrician as well as the general practitioner.

From a large personal experience I feel that its importance can not be exaggerated, nor its seriousness underestimated. I take occasion to emphasize the subject for the reason that, though I have frequently spoken of the many annoyances following operation in consequence of the employment of the catheter, it still strongly appeals to me.

Infections of this nature unnecessarily prolong convalescence, occasion a great deal of distress and pain, increase the attentions to be bestowed upon the patient, as well as add to the anxiety of the attendant. Not infrequently the infection extends beyond the posterior urethra and bladder to the pelvis, even endangering the life of an otherwise convalescent patient.

Despite the modern aseptic and antiseptic methods employed by every careful practitioner, we are confronted by a condition in which these prophylactic methods seem ineffective as a preventive means. When one considers that the muscularis is in a paretic state, the mucosa turgid from over-distention, and the patient often in a condition of diminished resistance, we can readily apprehend an exaggerated receptivity to the various bacterial flora.

It does not necessarily follow that the infection is always from without; it may be from within; the contaminating germ may and does reside in the contiguous bowel; the colon bacillus may even find entrance where the catheter is not employed. Of these infections it is not my purpose to speak. They form such an indefinite minority of the cases under discussion that their possibility is only mentioned.

In the vast majority of instances the nurse or attending surgeon has failed in the details of rigid asepsis.

That these infections are much more common than is generally believed is due to the fact that many of them occasion but little annoyance, and eventually recover without interference. Some, even, may pass entirely unnoticed. I am quite sure that if any case requiring catheterization a number of times were closely examined for the evidences of a posterior urethritis, or cystitis, the presence of pus in the urine could be much oftener demonstrated than is now believed. All operations about the pelvic organs and especially the rectum and anus, are very apt to cause retention; scarcely one patient out of a dozen escapes. It is well known that while some may require but one or two introductions of the catheter, there are others in whom retention may continue for a week.

It has been my unfortunate experience to observe the results of a mal-adroit procedure to produce a much more serious trouble than that for which the operation was undertaken. That these things may impair the confidence reposed by the patient in the practitioner, to say nothing of his personal chagrin, goes without saying.

I well remember the instance of an old lady, suffering from an impacted gallstone in the common duct. She had been jaundiced for more than a year, and very much reduced by constant pain, chills, fevers and sweats. Despite her grave condition, I had succeeded in removing the stone from the duct, and while on the way to complete and successful convalescence, more than a month distant from the time of operation, I was greeted with one of these surprises while the patient was up and about. The nurse who had catheterized her for a number of days fol-

lowing the procedure, deftly concealed from me the bladder irritability of which the patient complained. Suddenly she had a severe chill, a high fever and a pronounced renal crisis referred to the left side—a pyelitis from an ascending infection, due to catheterization. Fortunately, she escaped without instrumental interference.

It is assumed that everyone is perfectly familiar with the technique of catheterization, but, unfortunately, the fact that "a broken link weakens the entire chain" is not fully appreciated. Boiling or firing the instruments is supposed to be the *sine qua non*. Washing the hands and, after the ablution, cleansing the finger nails is, usually, deemed of sufficient importance. Cleansing the genitals, and even the anterior urethra, is usually not forgotten, but how often does the attendant fail to return to the basin for a second washing of his hands and fingers? Though the lubricant is thoroughly sterilized, the nurse not infrequently permits the catheter to dangle about the clothing or bedding, and thus robs the supposed asepsis of its efficiency.

With all of these details observed, the number of infections would certainly be minimized, but there yet remains a small minority, where, despite all these precautions, infection is certain to follow, owing to the causes already mentioned.

It would not be amiss to follow the plan adopted in the Viennese General Hospital as a prophylaxis against ophthalmia neonatorum, to drop a two per cent solution of silver nitrate into the urethra, as was done into the conjunctival sac. The treatment is extremely simple. When once the condition is recognized, an instillation of two or three per cent of silver nitrate solution, after emptying the bladder, will act like a charm, sometimes requiring but ten or fifteen minims to accomplish the result, and when noticed sufficiently early, two or three such instillations practised daily will most certainly achieve the result. Other silver salt substances may be employed, but a personal experience assures me that the nitrate is the most efficient and certain of all, nor is it painful if properly practised. Internal remedies can be dispensed with.

[Written for the MEDICAL BRIEF.]

Neurasthenia—Its Etiology and Treatment.

BY L. HERBERT LANIER, M. D.,
St. Louis, Mo.

Impressed, as I have been, by the frequency with which general practitioners everywhere have to treat neurasthenia, it causes no little speculation on my part to explain why this subject is so infrequently discussed by medical men in their society meetings.

There is no other disease recorded in the dictionary of pathologic phenomena which presents such a variety of symptoms, and whose symptoms are so misleading and cause so many errors in diagnosis, as neurasthenia, considered from a general practitioner's viewpoint.

Neurasthenia is a condition of nervous prostration or nervous exhaustion, attended by many variable and inconstant subjective symptoms, and a few significant objective phenomena. It is brought about by a neuropathic tendency, combined with overwork or exertion of any kind, excesses, traumatism with fright, and chronic diseases; or perhaps a better definition would be, a debility of the nervous system, causing an inability or lessened desire to perform or attend to the various duties or occupations of the individual. Professor Bartholow describes it as consisting "essentially in an exaggerated susceptibility to bodily impressions and false reasoning thereon."

Causes.—The causes may be grouped as hereditary and acquired. We shall first consider the cases coming to us which point to hereditary origin. We do not all start in life with the same amount of nerve capital. Parents who have led irrational lives, indulging in excesses of various kinds, or who have been the subjects of nervous complaints, or of mental trouble, may transmit to their children an organization which is defective, because of the absence of "nerve force."

Such individuals start handicapped with a neuropathic predisposition, and furnish a considerable proportion of our neurasthenic patients. Or, as Van Geison puts it: "The potential energies of the higher constellations of their association

centers have been squandered by their ancestors." We must also consider those cases in which, during intra-uterine life, there have been conditions which interfered with the proper development and nutrition of the embryo. Then there are forms of hereditary neuropathy, caused by injury to the germ-plasm, derived from one or both of the parents, and as Osler euphoniously puts it: "So long as these individuals are content to transact a moderate business with their life capital, all may go well, but there is no reserve, and in the exigencies of modern life these small capitalists go under and come to us as bankrupts."

There is one other condition which plays more than a minor role in the etiology of hereditary neurasthenia; that is the indifference manifested by the majority of women concerning the future welfare of the embryo, after its escape from its intrauterine prison. Of course (notwithstanding its efficaciousness), all women, during pregnancy, can not be surrounded by beautiful paintings and inspiring sacred melodies issuing from myriad-tongued musical instruments and from the vocal cords of such renowned singers as Patti and Bernhardt; yet there are few who can not, by the exercise of sound judgment and will power, manage to control their temper and ward off nerve storms which result so disastrously to the nervous system of the embryo which, when it reaches maturity, if it ever does, will present a picture analogous to those who stand in the shadow of lost hopes and fallen ideals.

Acquired Causes.—It may result from various chronic diseases, mental worry or emotion, overwork, as according to Jackson, "When the expenditure of nerve force is greater than the daily income, physical bankruptcy, sooner or later, results." A neurotic temperament, sexual excesses, alcoholism and the tobacco habit are contributing causes. The cares and anxieties attendant upon the gaining of a livelihood, in persons who have inherited a feeble organization, predisposes them to neurasthenia.

The older writers referred to neurasthenia as irritable weakness, and later spinal irritation seems to be the only term by which this condition was designated. Persons suffering from neurasthenia lose the distinction between essentials and non-essentials; things that would be regarded lightly by normal individuals causes then great annoyance, and the entire organism reacts with unnecessary readiness to slight stimuli.

Neurasthenia may follow the infectious diseases, particularly influenza, typhoid fever, and syphilis. The morphine habit may lead to a high grade of neurasthenia, though the drug habit is more often a result, rather than a cause, of the neurasthenia. Other potent causes, though less easily dealt with, are the worries attendant upon love affairs, religious doubts, and domestic troubles. The traumatic forms, especially those following upon railway accidents, while interesting, can not be discussed in the time allowed for this paper. The traumatic cases may be divided into three groups, simple neurasthenia, cases with marked hysterical manifestations, and cases with severe symptoms, indicating or simulating organic disease.

Symptoms.—The army of symptoms attendant on nervousness are manifested in their most aggravated form in neurasthenia. One of the earliest manifestations of nervous exhaustion is an irritability, or weakness of the mental faculties, as shown by inability to concentrate the thoughts, and efforts to do so causing headache, vertigo, restlessness, fear, and a feeling of weariness and depression.

There may be ocular disturbances, cardiac palpitation, coldness of the hands and feet, chilliness, followed by flashes of heat; followed, in turn, by slight sweating, insomnia or fatiguing sleep, accompanied by unpleasant dreams, are other conspicuous symptoms. Genito-urinary disorders are frequent in the male, with pains in the back, giving the dread of impotence; in the female is found a painful menstruation, ovarian irritation and irritable uterus.

The "neurasthenic stigmata" are: Feeling of pressure on the head, disturbances of sleep, pain in back, muscular weakness, dyspepsia, sexual disturbances, and mental disturbances. In all forms there is a striking lack of accordance between the symptoms of which the patient complains and the objective changes discoverable by

the physician. Hyperesthesia, especially to sensations of pain, characterizes almost all neurasthenic individuals. The sensations are nearly always referred to some *special* region of the body—the skin, eye muscles, the joints, the blood vessels, or the viscera. It is frequently possible to localize a number of points painful to pressure.

The so-called "irritable humor" is very noticeable, if such pathological sensations continue for a long time, and the mood and character of the patient gradually alters. Many obnoxiously egotistic individuals met with in daily life, are in reality examples of psychic neurasthenia. The neurasthenic is very dogmatic, and demands the greatest consideration for his condition; to merit his esteem and confidence his desires must be immediately granted. He may, however, have but little consideration for others, and some there are who derive much pleasure from making others unhappy.

The so-called "anxiety conditions" are always present in advanced cases. In the simpler forms of anxiety (nosophobic) there may be only a fear of impending insanity, or of approaching death, or of apoplexy. In many the anxiety becomes intense, and the patients are restless, and declare that they do not care to live; they may throw themselves upon a bed, crying and complaining, and making convulsive movements with the hands and feet. Some patients complain that a definite word, a name, number, a melody, or a song, is continually running through their mind, in spite of all he can do to abolish it.

In the severer cases of psychic neurasthenia, the so-called "phobias" are common; the most frequent form is agoraphobia, in which patients, on coming into an open space, are oppressed by an exaggerated feeling of anxiety; they begin to tremble all over, they complain of palpitation of the heart and compression of the thorax, profuse perspiration, and a feeling as though chained to the ground is another symptom frequently complained of. Others are afraid to be left alone (monophobia), or in a closed compartment (claustrophobia). Some fear people and society (anthrophobia). A series of other phobias have been described—batophobia, or fear that high things will fall; pathophobia, fear of disease, and astrophobia, fear of thunder and lightning. Occasionally, there are some who are afraid of everything and every one, victims of the so-called pantophobia.

The reflexes in neurasthenia are usually increased, the deep reflexes, especially, never being absent. There may be inequality of the pupils in neurasthenia. Of all the symptoms common to all types of the condition in question, introspection, with gloomy forebodings and depressed spirits, seem to be the most constant. They see the world in the light depicted in these verses from Longfellow:

My life is cold, and dark, and dreary;
It rains, and the wind is never weary;
My thoughts still cling to the mouldering past,
But the hopes of youth fall thick in the blast,
And the days are dark and dreary.

Our days are covered o'er with grief,
And sorrows neither few nor brief
Veil all in gloom;
Left desolate of real good,
Within this cheerless solitude
No pleasures bloom.

And fortunate, indeed, is the physician who can change these pessimistic views of his neurasthenic patient and force upon them the optimism contained in the following lines:

Be still, sad heart! and cease repining;
Behind the clouds is the sun still shining;
Thy fate is the common fate of all,
Into each life some rain must fall,
Some days must be dark and dreary.

Enjoy the spring of Love and Youth,
To some good angel leave the rest;
For time will teach thee soon the truth,
There are no birds in last year's nest!

Treatment.—I should like to speak of the prophylaxis, as it is of vast importance, but have not the time to consider it at present. There is no routine treatment for neurasthenia, since every individual is a law unto itself. In general, it will be the aim of the medical adviser to remove the patient as far as possible from the influences which have led to his downfall, and restore the equilibrium of the nervous system, which is always destroyed in neurasthenic patients.

Many patients come under our care too late for satisfactory treatment, but I shall outline the treatment for neurasthenia from its incipiency. The physician must

in the beginning inform his patient that without his co-operation, with regard to observing the rules of taking food, sleep, and mental work, little can be accomplished. Also tell him that it will take several weeks and probably months to effect a cure. By all means gain the confidence of the patient. While some physicians advise absolute rest, both mental and physical, I believe in all except the most advanced cases, moderate physical and intellectual exercises, alternated frequently with rest and the administration of food, is best.

Hospital or sanitarium surroundings, with judicious nursing, is to be desired. Hydrotheraphy is indicated in all cases; the wet pack for insomnia having advantage over all somnifacients. Salt baths, various forms of douches, partial packs, foot baths, all being invigorating. General and local faradization, galvanic electricity, and franklinization may be used in every case by skilled operators.

Treatment by drugs should be avoided as much as possible. Alcohol, chloral, cocaine or morphia should never be given. If anemia is present, arsenic and iron are indicated. Phosphorus is overrated. For pains and nervous attacks, the salts of ammonium, potassium and sodium are indicated.

Where the anxiety conditions are disturbing, cautious use of opium may be resorted to. Prolonged treatment with opium is, however, never necessary in neurasthenia, and should be condemned.

2527 North Taylor Avenue.

World-Wide Recognition.

We are pleased to call attention to the fact that an article entitled, "Medicine at the Time of Homer," written by N. Benakis, M. D., Smyrna, Asia Minor, and translated from the Greek for THE MEDICAL BRIEF by Dr. A. Rose, New York City, has been reproduced in two German journals. This article was printed in the BRIEF in November, 1906. It is gratifying to know that articles supplied to the BRIEF in original form have such a world-wide significance. It shows that the BRIEF is read in all countries on the globe, and that its articles are translated into all languages. The BRIEF is not only national, but international.

Medical Ethics.

BY S. E. GIBBS, M. D.,
New York City.

There is, perhaps, no subject in the broad domain of medicine that has been so much discussed, argued about, and wrangled over, from time immemorial, as the subject of "Medical Ethics." So that it may not be amiss to ask the question, What is medical ethics, and of what does it consist?

It would be impossible, in the short space allotted me, to give a full definition of ethics, the subject being too vast and complicated. It will be sufficient, however, for the present purpose, to define it briefly as the science of human duty, the science of right, and of right character and conduct; in other words, moral science.

Medical ethics, therefore, would mean the application of these principles to the relationship which exists between the various members of the medical profession and their conduct toward each other, and one of the objects of our various societies and associations is to further these principles, the foundation of which dates back as far as the golden rule, in obedience to which it is understood that every member of the profession should be ever careful not to infringe upon the rights, nor to endeavor in any manner to secure advantage to himself to the detriment of his fellow practitioners.

To all of the above propositions almost every member of the profession is ready to subscribe in the abstract. But in these practical days, competition being keen, and the struggle for existence intense, owing in great measure to the over-crowded condition of the profession, the vast combinations of capital in the various large hospitals, dispensaries, and other institutions, it becomes too often a question how far one may go in violation of those principles and still remain within the limits of the Code of Ethics. A very narrow margin, it is true, but still a margin, so that we see almost daily and in various ways a tendency to overstep the line. Sometimes it would appear almost involuntarily; sometimes, but more rarely, in-

tentionally, and it may be well to inquire in what ways this code of ethics is so often violated, and by whom? And first and foremost must be mentioned the modern hospital and dispensary. The original object of the hospital was to provide medical and surgical treatment for those unfortunate persons who were too poor to pay for the services of the physician or surgeon. Certainly a laudable object. But the times have changed. The hospital today is simply a first-class hotel, with medical attendance supplied free of cost. The dispensary still feebly welcomes the poor, but prefers the rich patient, and the proportion of the latter, or at least of those who are able to pay something, is greatly in excess of the former, as witness the vast number of patients treated in those institutions in this and other cities during the past year, according to their own published reports, and the treatment of every patient who was able to pay something, be it ever so little, was, in the opinion of the writer, a direct violation of the code, for it was done at the expense of the profession at large, the members of which were of necessity the pecuniary sufferers.

Another way in which the code of ethics is frequently infringed, is by the advertising in the daily newspapers of important operations which have been, or are about to be, performed on prominent persons, especially where the name and address of the operator is mentioned, thereby attracting undue attention to himself and his assistants.

In many of these reported cases every step in the operation, even to the smallest detail, has been minutely described, so that the inference is that the information must have been given to the reporter either by the operator himself or by one of his assistants, with the full consent of the former, for there is no record of any reprimand ever having been administered to the person giving the information, and the same assistants have, subsequently, participated in operations by the same surgeon, and with the same result.

Again, the issuing of bulletins in cases of sickness occurring in the family of wealthy or prominent persons. While it may be quite proper to inform the public of the progress of the patient toward recovery or otherwise, it is too often made a pretext for advertising and keeping in the public mind the names of the medical attendants.

Every physician knows that the frequent, very slight fluctuations of pulse or temperature in a severe case of illness means little, or nothing, yet in many of these cases a variation of even two-tenths of a degree in temperature, or an increase or decrease in the pulse rate in the slightest degree, is promptly telegraphed from one end of the country to the other, and the names of the doctors in attendance often occupy the larger space on the bulletin board.

The spirit of the code of ethics is also violated by the publication of long articles in the newspapers on surgical topics, sometimes giving a full description of the symptoms, progress, complications, indications for operation, etc., in some cases such details occupying half a page of a Sunday newspaper, and bearing the signature, not of some noted quack, but of a wealthy surgeon in good standing in several medical societies, while should the less rich and more obscure surgeon adopt the same tactics for the purpose of attracting attention to himself (who so much needs it), the result would be that charges would be preferred against him in his medical society, on the ground of unprofessional conduct.

The consultation also offers a wide opportunity for the infringement of the code. How often does it happen that the consulting physician ingratiates himself so thoroughly during his interview with the patient or his family that in subsequent cases of sickness in the said family the faithful doctor, who has been in attendance for many years, finds himself supplanted by the former consultant.

Among the lesser sins against the code of ethics (if such a distinction be permissible) is the indiscriminate distribution of reprints of articles on medical or surgical subjects, carelessly or purposely mailed to patients, or placed in large numbers in the reception room in such position as to attract the attention of the waiting patient.

The "cipher code" prescription, intended to be interpreted only by some especially-designated druggist, while working injury

to the neighboring druggists, most of whom are honorable men, also reflects upon the medical profession to some extent by creating in the mind of the patient the impression that the doctor so prescribing is in possession of some wonderful and valuable secret remedy, unavailable to other physicians.

The emergency call, in a case of accident, where the details are furnished to the newspaper reporter, together with the attending physician's full name and office address, even when these are not required and can serve no useful purpose, other than to advertise the doctor.

The presentation of the physician's photograph and biography or autobiography to the press reporter, to be published, together with those of the prominent men in a city, town, or county.

The giving of so-called "health talks" in public halls to miscellaneous audiences, which, though of some benefit to the public, is usually undertaken more for the purpose of attracting attention to the lecturer than a sincere solicitation for the welfare of the public.

The occupying of a front seat in church, and the hurried entrance during the service, in a breathless condition, medicine case in hand. The often unnecessary call-out during the service, or while in attendance at the theater, may also be classed among the minor infringements of the code.

To which might also be added the joining of so-called benefit societies, medical bureaus, surgical institutes, etc., for the privilege of attending the members thereof for the munificent compensation of one dollar a year per member.

All these and many other infringements of the medical code that might be mentioned, did space permit, are inconsistent with that respect for the code of ethics which should be felt by every member of the honorable profession of medicine.

[Written for the MEDICAL BRIEF.]

Homeopathy vs. Allopathy—Comparative Materia Medica and Therapeutics.

BY N. SISCA, M. D.,
Killarney, Queensland, Australia.

(Continued from page 227.)

X.

By far the most striking evidence of the steady and uninterrupted progress homeopathy is making, is the vast amount of material it has accumulated in its *materia medica* during the last thirty years or so. Time was, and not very long ago either, when all the *materia medica*, which it was thought indispensable for a homeopathic practitioner to know, was enclosed within the two hundred and sixty-three pages of a small book entitled "The Principal Uses of the Sixteen Most Important and Fourteen Supplementary Homeopathic Medicines," while now a mere glance at the three ponderous volumes of the "Dictionary of the Homeopathic Materia Medica," by Dr. J. H. Clarke, or at the four still more ponderous volumes of "The Cyclopedia of Drug Pathogenesy," without mentioning their respective repertories, is quite enough to bewilder any would-be student of homeopathy. For the matter of that, the homeopaths themselves are beginning to groan under the weight of their own wealth, and a few years ago one of them went so far as to say: "What constitutes our *materia medica* today is a chaotic accumulation of subjective symptoms, real and fictitious, which out-rivals in grotesqueness the imagination of a Kipling, and would confound the intelligence of a Judge of the Supreme Court." "But this," a cool-headed Hahnemannian would say, "is downright pessimism. There may be something like a *farrago divitiarum*, but surely we can be trusted to evolve order even out of that."

Be that, however, as it may, any allopath, who may be willing to learn for himself what homeopathy really is, need not be discouraged. Hughes' "Pharmacodynamics" is still in print, and though it has come in of late for a good deal of snubbing on the part of one and another, who, like ungrateful pupils, have somehow become ashamed of their humble,

but none the less worthy, pedagogue, it yet remains, so far as it goes, the most readable, intelligible and reliable book in the English language, that can be recommended as a guide to the study of homeopathy for a beginner.

Dr. Hughes defines the homeopathic *materia medica* "the record of the pathogenetic effects of the medicines used by homeopathy." All the substances, which, by their provings on the healthy, have made good their claim to be recognized as homeopathic remedies, have their place in it; and, as we have already seen, by pathogenetic effects is meant the symptoms produced by drugs in the human body in a state of health. We allopaths are just beginning to revive an old theory under a new name that, namely, of "pathogenic therapeutics," in the sense of adapting the treatment of disease to our knowledge of the way in which disease is produced, or, in other words, to our knowledge of the process of evolution of the various disturbances and alterations which in any given case culminate into the nosological entity called disease. But homeopathy has had its pathogenic therapeutics since the time of Hahnemann, only in quite another sense, viz.: that instead of trying to ascertain and follow step by step the mode of production of disease, which, by the bye, and as we all know only too well, is more easily said than done, homeopathy proves a drug on the healthy, thus producing an artificial disease; and after putting down to the credit of that drug the artificial symptoms it has thus caused, holds itself ready to use that same drug as a remedy for a case of real disease, whose symptoms happen to be the same as, or the nearest approach to, those of the artificial one. And this in accordance, not with Dr. or Professor So-and-So's theory, but only and solely in accordance with a principle, which homeopathy has adopted as the law of its practice, the so-called law of similars.

Let us now compare notes, as it were, for a moment, and see whether it is true or not that while homeopathy on one side has for over a century stood with its feet on the immovable ground of its fundamental principle, allopathy, on the other, has been slowly but surely turning round and round, until today a very important part of what homeopathy has always contended for, is, in substance, if not in as many words, plainly and fully recognized by allopathic lecturers and authors.

In one of the chapters on general therapeutics in his "Consultations Médicales" (1901), Dr. Huchard, the well-known cardiopath of l' hôpital Necker in Paris, after briefly reviewing the many theories of the genesis of disease, which from time to time have rivalled one another in directing and controlling medical practice in the past, says: "It is time we should shake off the yoke of the tyrannical doctrine which by always making of disease a consequence of the lesion has for a long number of years paralyzed our therapeutic activity. The lesions of arteriosclerosis are preceded by a phase of functional troubles, due to a state more or less pronounced of vascular hypertension. This is the so-called stage of presclerosis *when as yet there are no lesions*,* and, what is still more important, this is the stage when treatment is really efficacious in doing the only thing there is to do, namely, to ward off the impending exhaustion of the arterial system. * * * I am one of those who think with A. Robin that 'if the function makes the organ, it is the disease of the function that produces the lesion of the organ.'"

It is the function, then, that, according to those two among the foremost therapeutists of the French school of today, has the first claim to our attention, if we want to treat disease successfully. But how shall we know that the function of an organ is disease? We can only know it by a study of its symptoms, and this is nothing else but pure and simple homeopathy. As I said in my last note, homeopathy has always taken the clinical aspect of disease as its working basis, and here we have two highly accredited representatives of one of the most advanced medical schools in Europe proclaiming in language which can not be misunderstood, the paramount importance of clinical therapeutics. For over a century, from Hahnemann downwards, the homeopaths have been ringing in our ears that it is the symptoms of diseased func-

*Italics mine.

tions that can give us the most reliable, if not the only, clew to the knowledge of disease; that the study of symptoms is the "royal road" to rational treatment, and that there are innumerable cases in which disease exists without having yet had the time to produce lesions, and in which, therefore, symptoms are the only thing we have to depend upon. But we have called them heretics, and yet, alas! it almost seems as if all of us were going to become heretics before long.

The homeopathic *materia medica* contains the pathogeneses of over three hundred remedies, which, according to their therapeutic importance, may be divided into three classes: First, those which, owing to their wide range of action and the thoroughness of their provings, are mostly in demand in every-day practice, and which are called "polychrests," like aconitum napellus, belladonna, bryonia alba, etc.; second, those whose symptomatology is not so extensive and whose range of action is more limited, like baptisia, chelidonium, lycopodium, etc.; third, those which have only a few symptoms to their credit, like bovista, cicuta, mezereun, etc.

It has often been said that one of the reasons why allopaths should have nothing to do with homeopaths is, that the latter use medicines in their practice which nobody but themselves knows anything about, and it is no doubt true that homeopathy has called into being as remedial agents a large number of substances quite unknown to us, except perhaps by name and which, had it not been for that, would have remained useless. Thus among the pathogeneses contained in its *materia medica* there are those of about one hundred and thirty plants, of several metals in their simple metallic state, of viruses of serpents, vipers, spiders and bees, etc., with which we are as yet entirely unacquainted, except in cases in which homeopathic remedies have been "rediscovered" by allopaths; but why this should be alleged as a reason for our ignoring homeopathy and the homeopaths I can not see. Their books and periodicals are accessible to everybody, and if the medicines they use and the way the use them are unknown to us, that is n fault of theirs.

Homeopathy has no purgatives, a tringents, hypnotics, sudorifics, diuretic etc., as such. The use of a drastic o cathartic medicine, as we understand i is incompatible with the principles o homeopathy. There are numerous home opathic medicines which are used as rem edies for constipation, but they are s used because among the symptoms whic they produce when given in large dose there is constipation, such as nux vomica bryonia, opium, plumbum, etc. In cases however, in which prompt and thorough emptying of the bowels is urgently re quired, the homeopathic physician resorts as a rule, to enemata.

Astringents, in the sense of anti-diar rheics, are not needed in homeopathic practice; but there are plenty of remedies in the homeopathic *materia medica* which are used to check diarrhea, and among them are to be found a good few of the medicines which we use as purgatives, like aloes, jalap, magnesia, mercurius, podophyllum, rheum, etc.

Homeopathy uses our hynotics to keep people awake, like opium and chloral, for instance, in sleepiness and such like complaints, and so forth, but I do not think it is correct to say that the homeopathic *materia medica* contains no stimulants, sedatives, antispasmodics or anesthetics. What are nux vomica and bryonia in their action on the intestines but stimulants, and belladonna, hyoscyamus and stramonium but sedatives? Where is a better antispasmodic than cuprum, and what is cantharis in its action on burns but an anesthetic?

Finally, a word about "repertories," or "finding-means," as Dr. Hughes calls them. A repertory in homeopathic literature is a sort of companion to the *materia medica*. The difference between the two is, that the *materia medica* under the heading of a remedy gives a list of all the symptoms caused by it, while the repertory under the heading of a symptom gives a list of all the remedies which have that symptom in their pathogenesy.

[Written for the MEDICAL BRIEF.]

Irritations of the Respiratory Mucous Membrane.

BY EDW. C. ROTHROCK, M. D.,
Palestine, Texas.

In respiratory diseases, such food should be used as judgment and experience would dictate, and, of course, food to suit the taste of the patient. Water, acidulated lemonade, should be allowed, and is very pleasant and of benefit to the patient. Food should be given in small quantities and at short intervals, every two or three hours, as required to maintain the vital powers. If food is given in excess it will do harm, distress the patient by fermentation and flatulent distention of the stomach and bowels, and impede the already embarrassed respiration, and when the blood is surcharged with nutritive material a further burden will be placed upon the lungs in the effort for its assimilation. No food or drug should be used that would irritate, nauseate the stomach and interfere with the appetite, digestion and assimilation, for the vital forces must be maintained, an excess of food avoided and care taken as to its quality. Depressing drugs have often, in children, caused untoward effects, as they are very susceptible to such action. In some cases respiration becomes greatly embarrassed, circulation fails, which is evident by rapid and labored breathing, and cyanosis is present, caused by carbon dioxide. The high temperature and inflammatory action increase more and more, embarrassing the respiratory organs and the functions of the heart. Great strain is put upon the lungs and heart, which already are doing double duty. The blood not being properly oxidized in the lungs a failure of the respiration is evident, and untoward effects will take place without relief.

A failure of respiration is more to be dreaded in children than heart failure. Stasis of the lungs must be prevented by stimulating the heart, drawing the blood into the arteries as much as possible from the veins, and thus relieve to some extent the engorged venous system and the obstructed pulmonary organs. Alcohol undoubtedly is the best stimulant, particularly for children, and is preferable to others. A child of one or two years of age can have ten to twenty drops of whisky—according to age and conditions existing—diluted with water, and sugar added; a little nutmeg will be of advantage; this given every one, two or three hours, of course, to be increased or diminished, according to the urgency of the case. If great prostration or septic condition alcohol is of the greatest benefit in maintaining the tonicity of the heart, hence sustaining the vital forces. Alcoholic stimulants should not be given in doses of over one or two ounces in three or four hours to adults, for over that amount will not be oxidized and will, perhaps, do harm. In simple attacks alcohol should be used, if at all, with caution, and cases which frequently occur when it will not be needed. A saturated tincture of camphor, one-half to two drops, for children; adults two to five drops, every one or two hours, in depression, is a valuable stimulant. Caffeine often has a good effect; dose for children, one-sixteenth to one-eighth grain; adults, one to five grains. Caffeine in small doses stimulates the heart, quickens its action, raises blood pressure, stimulates cerebral functions, is a diuretic by stimulating the secreting apparatus of the kidneys. Large doses have a different effect, depress the heart and respiration, pulse becomes small, irregular and intermittent. Larger doses paralyze the cardiac muscle and its motor ganglia, and death is by paralysis of respiration. As a stimulant, I prefer alcohol, and particularly for children. Next to alcohol, the nitrites, nitrite of sodium; its action is similar to nitroglycerin. It is very useful in the treatment of epilepsy, asthma, angina pectoris, and attacks of cardiac dyspnea. Nitroglycerin, in small doses, is efficient in respiratory neuroses, as asthma, whooping cough, laryngismus stridulus, etc., and lasting in its effects, producing great vascular dilatation, and hence lowering blood pressure by paralyzing the vaso-motor center, emptying the veins into the arteries, as it were, and relieving the right side of the heart, and, therefore, the engorged condition of the lungs. A child one or two years old could take of nitroglycerin one two-hundred-and-fiftieth to one three-hun-

dredth of a grain every two or three hours, as indicated.

Nitroglycerin, in large doses, produces tumultuous action of the heart by relaxation of its inhibitory apparatus and impairment of the ozonizing function of the blood. Therefore, it should be administered in very small doses. In some cases I prefer nitroglycerin to digitalis, or strophanthus, as the last two produce blood pressure. A good stimulant to the heart and respiratory functions is sulphate strychnine, one four-hundredth to one-five-hundredth can be given to children every two, three or four hours. It stimulates the nervous system, produces blood pressure in small doses, but in larger doses it lowers blood pressure as tolerance is had. It is seldom that I use strychnine for children, as I prefer other remedies.

Jewish Physicians of the Past and Present.

BY OSWALD W. KATZ, M. S.,
Boston, Mass.

The ancient Hebrew regarded health and disease as emanating from the same divine source: "I kill and I make alive; I wound and I heal" (Deut. xxxii., 39), said the Lord through his servant Moses; and, therefore, they who administer to the health of their fellows are regarded as the messengers of God, as the executors of His will. Joseph employed house physicians (Genesis i., 2) and Isaiah mentions a surgeon and wound-dresser (Isa. iii., 7). Afterwards the status of the medical profession became still more exalted. The court of justice employed in certain cases the services of a physician, whose expert testimony was decisive in criminal matters. Corporeal punishment was inflicted under the supervision of a physician. No physician was permitted to practice without a license from the local judicial council. Every city was required to have at least one physician.

The medical profession, at that time, received comparatively large fees. A current saying was, "A physician who takes nothing is worth nothing."

The subcutaneous stretching or cutting of the cord and obliteration of the testicle by means of gradual pressure is reported in Lev. xii., 24. In an accident in which the abdominal viscera were protruding through a wound, the position of the organ was effected automatically by frightening the patient, which caused the abdominal muscles to relax. After this the external wound was closed by sutures.

Harun al Rashid (789-806) was the founder of a medical university in Bagdad. He and his associate professors were Jews of the highest class and the best medical knowledge. Of course, it is impossible to classify all Jewish physicians at that time, but it is a well-known fact that the Cæsars of the Roman empire, the Kings of Spain and of other countries, employed Jewish physicians for their own service and the service of their households. Even the Popes, as Boniface VIII, had Jewish physicians. Bishop John I and his successor, John II, permitted a woman, Sarah Seligman, to practice medicine in Austria.

The Jewish and Christian church were all opposed to a desecration of the human body, such as proper anatomical investigations would have required. The German Emperor Frederick II (1212-1256) permitted dissection, but Pope Boniface VIII prohibited it.

The French Revolution brought a great change in the status of Jewish physicians. Jews were admitted to study in all universities and practice their profession. Even in Russia today many Jewish physicians are found, but it is especially in England, Germany, Austria and the United States that Jews have become prominent as general practitioners, specialists, university professors of medicine and medical journalists.

The first Jewish physician mentioned in colonial times in the United States is Jacob Lumbroza, who practiced medicine about 1639 in Maryland. The number of Jewish physicians in the United States is very large; but only a few, mainly those who have acquired some high official position, can be mentioned here. The physiologists, D. Reisman, R. Stein; the pathologists, A. Abrams, I. Adler, S. Fexner; the surgeons, W. Meyer, Joseph Raushoff, N. E. Bull, Solis Cohen, A. Jacoby, I. Loeb, and the Surgeon-Gen-

eral of the United States Marine Hospital service, R. Weyman.

Most Jews are inclined to follow the regular teachings of medicine, but recently the homeopathic medical colleges are reporting a great number of Jewish students.

In the present strife for success, in the battle of life, we do not recognize any more race or religion. It is "all for one, and one for all!" I, myself, have the honor to serve in a homeopathic institution, where, among three hundred physicians, nurses, etc., I am the only Jew, but I can pay the highest tribute to those disciples of our divine profession that never in my sixteen months' service have I ever heard an utterance against my race or my religion. Doctors and nurses stood by me in joys and sorrows, always anxious to give a helping hand; but, of course, this is "the land of the free and the home of tne brave," so thank God for America.

[Written for the MEDICAL BRIEF.]

On Single Remedy Dose Treatment.

BY C. B. KING, M. D.,
Atlanta, Ga.

What is eclecticism? What is an eclectic physician? I understand he is properly of that class of physicians educated, not only in diagnosis of diseases and symptoms—pathological—but in chemistry, physiology, anatomy and surgery; but fully taught medical therapeutics that he may be able to administer, as in his own skilled judgment, just such remedies as he may select or elect in his mind, from education, observation and long experience such remedies alone or in proper combinations will relieve—not the symptom which only indicates, as smoke does where the fire is, and not the cause—for cold weather may have been the cause—but to relieve the deviation and nature cures. Medicine never did cure anything. We can unload the stomach with a little apamorphia or lobelia, ipecac or sulphate of zinc, as we may select or choose; we can empty the bowels with cathartics or enemas. We can tranquilize the nervous system. We can equalize circulation, thereby giving nature a chance to relieve congestion, pain, etc. We can open the pores almost at a touch with properly prepared hot sponge bath energising them to active functions, and thereby nature will rapidly eliminate pent-up toxins, leucomains, or ptomains from our patient's system. We can strengthen nerve energies of an enervated system. Assist digestion, improve the metabolic process, but after all *vis medicatrix naturæ* has to do the curing or healing. All the salves in creation will not heal a sore; they do good, no doubt, properly compounded and applied, but old nature heals herself. So what I am trying to do is to iconoclasticly "rip 'em up the back," or knock down some men's ideas about giving eclectics—professors in colleges—editing eclectic medical journals, proposing to teach the young who want to become the healers of the sick when we old fellows, with our fifty years' experience, have passed away. And these very bright, well-educated young men know no better than to believe what they are taught by such "three-wheeled wagons" in their lectures, and in their journals, that you must give only one single remedy at a time. If that does not *cure*, then try another. You have plenty to draw from. Yes, but what becomes of the patient while you are practicing on him. He may cease to draw his breath. Then the papers will say he died after all that medical skill could do for him. And next day the minister—good man—will say his course in life was run; his time to go had come; he has gone to rest—the good Lord had called him home. And the doctor goes off, whitewashed, no doubt, hoping that he may do better with his next case. And he is taught to give a single remedy in a common or severe persistent sore throat, or slight persistent tonsillitis. If you give aconite, give it only. If you give sanguinaria, give it alone. If you give echinacea, give it alone. If you give stillingia, give it alone. Be an eclectic. If you give collinsonia, give it alone. If you give phytolacca, give it alone. Syrup wild cherry, give it alone. When I will take all of these properly combined in medical doses, put up in syrup of wild cherry, so as to give one teaspoonful every two hours, and invariably the patient (with few grains calcium iodide three times a day, with hot Epsom

salts, both at bedtime, and dose of Epsom salts in the morning), will soon be entirely well.

Our argument to the student or young doctor who is trying to learn after he leaves college, where he should be thoroughly skilled or taught, if necessary to relieve the sick, to combine a dozen therapeutic agents to overcome any deviation from a normal condition. But he is told if he gives more than one remedy at a time he can not tell which cured his patient. What does the patient know or care what helped him. It is relief he wants. What should the physician care, only to know that he does know by the pulse, the color of the eyes, the ears and skin, temperature and respiration, without looking at the tongue or asking a question, whether it is retention, invasion or enervation, or two of these three only natural causes for disease; and how to restore normal conditions with a rational treatment, once learned or correctly taught to him, will never be forgotten, and will ever serve him faithfully. But this single remedy doses so-called eclecticism, which is not so any more than Dunglison's definition of eclect meaning a "quack," reminds me as if they are afraid of our taxing the system with several different congenially indicated specific remedies combined, or of fearing to feed a man meat and bread, both at the same time, for fear of overtaxing the digestive apparatus; so we will give some bread—when it is writ, "Man shall not live on bread alone," then, in a few minutes, give some meat; and after a little while, at proper intervals, all day, will give potatoes, rice, chicken, turkey, pie, cake, pastry—all separately, to give nature a chance to digest and properly dispose of each, as it would be a great task for her to take hold of all these at once in the stomach. What folly, what absurdity, to think of not giving two or more purely congenial or compatible and indicated remedies at the same time. And the trouble with that professor and that school who are working so hard to get their young graduates to use single remedies in order to know which cures, when, perhaps, the single remedy did not open the pent-up pores, dilate the constricted capillaries, tranquilize the nervous system, neutralize the ptomain, open up the alimentary canal and let the patient get well. In proper combination of congenial remedies in pneumonia, for instance, all this can be done in the first, or congestive stage, and your patient can be cured in a few hours, and not have to pass through the second and third stages. And so with pleurisy, bronchitis and la grippe. Colic, whether hepatic or nephritic, also that dangerous thing, acute indigestion, relieved in a few minutes when the single remedy man would cause a funeral to take place; yet he may have done, and no doubt did, the best he knew. He had been taught that way. But he will soon learn better (at the cost of his patients), and will regard the teachings of those of his alma mater in their proper light—darkness.

[Written for the MEDICAL BRIEF.]

Gonorrheal Rheumatism.

BY SILAS HUBBARD, M. D.,
East Aurora, N. Y.

I will offer a reason and ask others to give a reason in the BRIEF why more men have the above-named complaint than women.

The reason, I suppose, is because the gonococci have easier access to a larger area of space of provender than in men.

The gonococci in women, besides having an easy access to the urethra, as in men, also have free access to the whole vagina, and then have free access to the internal structure of the uterus, and from thence through the fallopian tubes, causing salpingitis, etc., while with men the gonococci have to seek other structures, consequently their joints oftener become affected. Indeed, I have seen men very much crippled by the infection by a woman, while said woman went free from being crippled. It should be a warning to men not to expose themselves to the disease.

I received a copy of the BRIEF, and it was with pleasure that I read it. As a result, inclosed find one dollar for 1907. —FREDERICK DUGDALE, M. D., Sunny Brook, Md.

[Written for the MEDICAL BRIEF.]

Prescription and Proprietary.

BY C. S. CARR, M. D.,
Columbus, Ohio.

A proprietary medicine is a medicine the sale of which is, in some measure, controlled by the person who devised or formulated it. For instance, suppose some doctor has a recipe which he has used a great deal, and found it to be very efficacious in certain diseases. He finally concludes to manufacture the recipe on a large scale, and furnish it to the drug stores, with directions for use. His medicine would then be called a proprietary medicine. So long as the doctor continued to write the recipe, give it to his patients, and allow them to get it filled at the drug store, it would not be called a proprietary medicine.

As to the difference between a proprietary medicine and a prescription, there is no difference at all in which the patient is interested. If a doctor prescribes over and over again a formula which he finds very useful, he is doing exactly the same thing, so far as his patients are concerned, as if he had prepared the medicine himself and furnished it directly to his patients.

The main reason that certain doctors object to proprietary medicines is that the patient can go to the drug store and get a proprietary medicine without consulting a doctor. The doctors object to this, many of them conscientiously.

There are several objections. It is assumed, on the part of the doctor, that a patient is not competent to select the remedy he needs without a doctor's assistance; that he should first go to the doctor, not only to find out what his disease is, but to receive instruction as to what remedy or remedies he had better purchase.

But even where the patient already knows what his disease is, has gone to the doctor many times, and different doctors have told him what his disease is, so that there is no necessity for him to receive diagnosis, the doctor would still contend that he is further needed in the selection of remedies.

When the patient can go to the drug store, however, and find a medicine already prescribed for his disease, by a doctor, accompanied with directions for use, there is, in reality, no need for the patient to see any doctor.

It is usually a doctor who first compounds a proprietary medicine. Let us say it is a medicine for rheumatism. He generally has had extensive experience in treating rheumatism, and has found some combination of drugs especially efficacious. He puts up the remedy, and gives ample directions for its use, in plain English, and if the patient already knows he has rheumatism there does not seem to be any valid objection to his going directly to the drug store and purchasing the remedy for himself. Indeed, there is no objection, if the interest of the patient only is consulted.

It is to the doctor's interest, in many ways, that the patient should consult him every time he gets a medicine at the drug store. The doctors have always objected to patients getting prescriptions refilled. When a doctor prescribes a remedy for a patient he does not like to have the patient go back to the drug store and get the bottle refilled, even though the medicine has helped him. He prefers to have the patient come to him each time he has the prescription refilled, so he may be able to judge whether the patient should take that particular prescription any longer, or whether a change should be made.

In many cases this is, doubtless, a benefit to the patient. Sometimes the doctors are obliged to prescribe narcotics or nervines. If a doctor is wise he does not care to have the patient use such medicines long enough to acquire a drug habit. If the patient is allowed to go to the drug store and get the prescription filled as often as he pleases he might, unwittingly, get into the habit of taking a narcotic. Indeed, this often happens, and the doctor is, therefore, justified in his opposition to the practice of getting prescriptions refilled. But when the doctor prescribes something that does not contain any narcotics or objectionable drugs, something that can be taken indefinitely without danger of producing a drug habit, there is practically no objection to the patient's

getting the prescription refilled as long as he thinks he needs it.

If a patient has been told by different doctors that he has rheumatism, and some doctor has devised a remedy for rheumatism, manufactured it, and placed it in the drug store for sale, with directions for use, there can be no possible objection, from the standpoint of the patient, to his going to the drug store, buying this other doctor's remedy, and taking it as long as he finds it helps him.

The doctors object, however, chiefly because every such patient is a loss to themselves. If the patients get in the habit of going to the drug store and purchasing outright remedies for rheumatism, or dyspepsia, or catarrh, or any other chronic disease, then the doctors, of course, would lose a great many valuable customers. They prefer to have the patient consult them every time he gets medicine, because each time the patient consults them they get a fee for the consultation.

"But," it might be said, "surely the doctors would not plead guilty to such a selfish motive as this. They must have some excuse for taking such an attitude towards the interest of the patient. What do they say to justify their attitude?" The doctors say something like this: That even if a patient knows he has rheumatism, it does not follow that any one remedy for rheumatism should be continually taken. They say that the disease should be treated from time to time for such changes as are indicated by the patient's symptoms. A very excellent remedy for rheumatism might do for a time, and then some change would be indicated which would cause the doctor to alter the prescription he is giving, in order to complete the cure.

Patients, as a rule, do not know what they are taking when the doctor prescribes for them. It is the doctor's opinion, generally, that a patient ought not to know what he is taking. They think that a medicine operates better if the patient does not know, and they prefer to keep the patient in utter ignorance of the remedies they prescribe.

I do not think, however, there is any advantage in keeping a patient in ignorance as to the medicines he is taking. I think he would be better for knowing what he is taking. I believe the peo ought to be treated as if they were intel gent beings. If, for instance, iodide potash can be relied upon to cure certa constitutional diseases, the patient oug to know he is taking iodide of potash. least, he ought to know the name of t mixture, if it be a mixture, so that case it helps him he can not only get for himself, but can assist others in g ting it. When the patient does not kno what he is taking, then in case the me cine helps him he is no wiser than was before. If he should again be a tacked by the same disease, he would obliged to go to the doctor again, for h experience has taught him nothing as remedies.

Another disadvantage is, if the patie is ignorant of the medicine he is takin but the medicine makes him worse, i stead of better, and he finally conclud to change doctors, the second doctor liable to give him the same medicine th first doctor gave him. Of course, th medicine may be slightly different in tast and color, and somewhat different in it effect, but he is very liable to get pra tically the same medicine that the othe doctor gave him. If the first doctor ha told his patient what he was taking, o if the patient had in any way learned th name of the mixture, it would be bette for him, because then he could refuse t take the same medicine after he ha once given it a thorough trial.

It is a pitiful sight to see patients go ing from doctor to doctor for some chroni ailment, changing doctors every now an then, but receiving from each doctor prac tically the same treatment. The patien is in the dark all the time. He did no know what the first doctor gave him. H did not know what the second doctor gav him, and so he may go on until dooms day changing doctors without, in reality changing his treatment.

This would not be so if the patient were allowed to go to the drug store and buy the proprietary medicine, the name o which he knows. For, having bought one bottle and tried it, if it does not help him he can forever afterwards refuse to take the same medicine again, for experience has taught him that it does not help him. The next time he buys a proprietary medi

cine for his ailment he will naturally buy a different one, and in all probability would get a different mixture. The people are made wiser and wiser by their use of proprietary medicines. They try one remedy for rheumatism. If it does not help them they need never purchase that remedy again. They then select some other remedy, that has a reputation for curing rheumatism. If that remedy also fails to help them, they can select the third. Each experience makes them a little wiser as to what remedies will not help them.

The so-called ethical doctors are practically agreed in their opposition to letting the patients know anything about their treatment. To keep the people in the dark as to remedies is considered to be medical ethics. To undertake to instruct the people through pamphlets or printed matter of any sort, to undertake to advertise to the people any remedy, no matter how good, no matter how honest the advertisement may be, is a grave offense against the profession.

The doctors who put up proprietary medicines try to instruct the people. At least, they intend to. Many of them may be unfit to give such instruction, and it is barely possible that some of them intentionally mislead the people, but in the main the doctors who manufacture or prescribe a proprietary medicine try to make their patients more and more intelligent as to the use of medicines. Such doctors furnish their patients with pamphlets and other printed matter, calculated to instruct them as to diseases and remedies for disease. Such doctors have often written, at great expense, medical books for use in the home. These doctors have often rendered great service to humanity by the clear and truthful descriptions they have given of disease, and the simple, home-made remedies for their cure.

The chief controversy between the doctors who make and prescribe proprietary medicines, and the doctors who write prescriptions, is that the first class of doctors believe that the people ought to be instructed in matters of disease and cures, while the second class of doctors believe that the people ought to be kept in ignorance. To keep the people in ignorance is, in brief, what is now known as medical ethics. To enlighten the people is what the ethical doctors call quackery and charlatanry. Any doctor who would write a book or edit a magazine calculated to instruct the people how to cure disease would be considered a quack. He would immediately lose his professional standing, his name would be dropped from medical societies, and he would be considered by the ethical doctors as a disreputable doctor.

There are many ethical doctors who use proprietary medicines. In fact, they are using proprietary medicines more and more every year. There is probably not an ethical doctor who does not, occasionally, prescribe proprietary medicines.

The difference between the proprietary medicines which the doctors prescribe and the proprietary medicines to which the doctors object is simply this, that the proprietary medicines to which the doctors object are so advertised that the people read the advertisements, while the proprietary medicines which the doctors approve of are so advertised that the people do not read the advertisements, and often the advertisements are put into such language that the people would not understand them, even if they should read them.

The proprietary medicines which the doctors approve of are advertised chiefly in medical journals. They are also advertised, each manufacturer for himself, by sending circular letters, printed slips, booklets, etc., in great numbers all over the world.

These advertisements are not sent to the people. They are sent to doctors only. To advertise a proprietary medicine to doctors only, to advertise it in the medical journals chiefly, meets the approval of the ethical physician, simply because such advertising does not help to enlighten the people, but serves only to help the physician himself.

The proprietary medicines which the doctors approve of are sold to doctors only, and if the people desire to get one of these proprietary medicines they must first go to the doctor, pay him for prescribing it, and then afterwards go to the druggist and pay him for the medicine.

[illegible] which
[illegible] drug store
[illegible] but not
[illegible] is a subject
[illegible] to legis-

[illegible] objection, on the
[illegible] of a proprietary
[illegible] on each bottle or
[illegible] of the ingredients
[illegible] but I doubt if this would
[illegible] purpose for which it is
[illegible] people who use proprietary
[illegible] nothing about the ingredi-
[illegible] They are interested only in how
[illegible] medicine operates. If it cures them,
[illegible] and they want. The people do not
[illegible] to study pharmacy or *materia medica*. They are seeking a cure, and want only such information as assists them in finding a cure. It would render no assistance of this sort to put the names of the ingredients upon the package that contains the medicine. Such names, if correctly given, would be to the people only a confusing mass of jargon, and would throw no light whatever upon the subject. In the present state of affairs, however, it would be wise for the owners of proprietary medicines to put the whole formula upon the bottle, in addition to simply putting the per cent of ingredients, which the Government, in the pure drugs act, has thought best to regard as harmful.

I do not believe there is much fraud practiced in the manufacture and sale of proprietary medicines. Generally, the manufacturers of patent medicines are wise enough not to attempt any such thing. They have too much money invested in such an enterprise to dare to practice any harmful or glaring fraud. There may be such attempts made, occasionally, but the firms practicing them very quickly go to the wall. The people are quick to see fraud, and will not purchase anything they have tried and found wanting. Advertisements may sell fraudulent products once, but no one will consent to be defrauded the second time. Unless a medicine gives sufficient satisfaction, so that it will be purchased over and over again by the same person, it does not pay to advertise it.

I would have laws against the practice of fraud, and there are already such laws. Plenty of laws. They should be enforced to the letter. Any attempt on the part of a patent medicine manufacturer to defraud the people, any misstatement or overstatement, any pretense or insincerity, should be swiftly and severely punished. But the complaint should come from people who have been defrauded and not from rival professional sources.

I do not advise the use of any medicine but I advise every one to be guided by his own experience. If a man wants to take medicine he should be allowed to do so. If he prefers to employ a doctor every time he is sick, no hindrance should be interposed. If he prefers to make the attempt to inform himself, to select his own medicines, independent of the doctor's advice, he should be allowed to do so. It is a great mistake to attempt any legal regulation of such affairs.

I regard the medical profession as mainly composed of men who are honestly trying to do a square business, and are conscientiously trying to heal diseases and please their customers.

As to whether this is more true of doctors in this country than in other countries, I believe that the average American doctor is more courteous, more disposed to treat his patients as if they were intelligent beings, than the physicians of other countries. The reason for this is that in the past the relation of the doctor and the patient has been allowed to adjust itself without much legal interference. In the countries like Germany, where everything is dictated by law, the physician, as a rule, is insolent to his patients, and treats the average patient as if he were a dog or a goat. This is the legitimate result of medical legislation.

I believe that if medical legislation goes on in the direction it is now started, it will finally produce an unfavorable result upon the profession in this country. This will create a state of affairs in which arrogance and laziness on the part of the physician will be encouraged, and a

spontaneity and growth of the healing arts discouraged.

I would confine all medical legislation to the regulation of fraud. If any more laws are needed to punish fraud they should be passed. But I do not think that any more laws are needed. All that we need is the thorough execution of such laws as we have. Every doctor should be held responsible for his mistakes, regardless of diplomas, regardless of schools of practice. It should be made easy for the people to protect themselves against carelessness and ignorance. But, while this is being done, the people should be left absolutely free to choose their own medicine, to select their own doctors.

The practice of medicine has always been experimental, but by experiment a little knowledge has been gained from time to time, so that the same old experiments need not be tried over and over again. Thus it is a few drugs have been found, by experiment, to produce the action of physic, and are known and can be safely relied upon for that purpose. So with a large number of drugs that operate in different ways. While the discovery of their use was experimental, and the discovery of the use of new ones is still experimental, yet experience has finally provided us with a large number of drugs, the action of which is known. But whether the action of any one of these drugs is beneficial or not still remains, and probably always will remain, largely a conjecture. Whether a physic, or an emetic, or a diuretic, or a hypnotic, ought ever to be used in any case of disease is still a mooted question, many doctors affirming it, and many other doctors of equal authority denying it.

Medicine is not a science, it is an art, and what knowledge the physician possesses is not gained by scientific deductions, but by experiment. No one can tell before trying what any new drug will do. Neither the chemist nor the pharmacist knows any more about the action of an absolutely new drug, or chemical, than a barbarian would know. Its action upon the human system must be determined by actual experiment.

If the practice of medicine were a science, or even partly scientific, these disagreements among doctors of the same school could not occur. What particular medicine shall be used in any case of disease depends largely upon the whim or habits of the doctor himself. The symptoms of disease are attended with great uncertainty, therefore disagreement is inevitable, and entire agreements are an exception rather than the rule.

The rapid decline in the use of drugs and patent medicines, and the war against their use in prominent magazines, is some proof of the statement that the entire system of medicine is, in a great measure, experiment. When a physician decides to change the treatment of a patient, as is often done, it is because his first experiment did not prove effectual, and he has decided to make another experiment. It is not possible for him to ascertain this fact in any other way except by experiment.

[Written for the MEDICAL BRIEF.]

The Study of Epidemic Diseases.

BY JOSEPH D. HARRIGAN, M. D.,
New York City.

It would be difficult, indeed, for the scientific medical man to find a subject more interesting and more absorbing than that of the epidemic diseases.

For ages it has engrossed the attention of the greatest and the humblest of scientific investigators.

Yet, seemingly, today we are no nearer the elucidation of the mysteries of these unwelcome visitors than were the great scientists of a thousand years or two ago. Whether or not the methods employed in investigating them have been faulty it is unnecessary to consider. It is sufficient to know that we have before us, in the study of these diseases, a broad domain for investigation, whose borders have been skirted by many but whose interior realms have been almost unexplored.

To obtain anything like a comprehensive view of epidemic diseases, it is not sufficient to simply study the diseases themselves, although a thorough mastery of them individually is essential. The most important results can only come from a consideration of their various relationships.

This must include a comparison of the diseases with each other, a consideration

of them with regard to their chronological order, and a close investigation of the connection between them and the various meteorological phenomena that appear to be bound up with many of their appearances. Confining our investigations to one disease at a time, and limiting our researches to what the eye-piece of a microscope might disclose, may do for an embryonic investigator, but to obtain a thorough knowledge of them requires that we take, as it were, a bird's-eye view of the whole situation.

There is a considerable difference obtained in results by viewing disease simply through a microscope, or rather the effects of disease, and those accruing from observation of all the circumstances that attend those diseases. As much difference, in fact, as obtains between the narrow, restricted view of a private in the ranks in a great battle, and the sweeping observations made through the commander-in-chief's field glasses. What appears to the limited vision of the former as of the utmost importance, in fact, the only thing worth basing calculations upon, to the latter simply appeals as one incident, of, no doubt, some importance, but still as only one part of the great picture.

So it is with our study of the epidemic diseases. Influenza, studied individually, furnishes in its symptomatology a wonderfully absorbing panorama of protean changes upon which to feast the eye, stirring up our mental activities at the same time not a little.

But nothing is accomplished towards elucidating the etiology of the disease by this method of investigation. We might just as well study for ages one star in the firmament. If its relationship with the others and consequently, the various influences affecting it, as likewise the results obtained by comparisons made between it and the other stars, are not carefully calculated upon, our conclusions will be far from being scientifically accurate.

The study of influenza by itself is very fine, but the study of it in connection with other of the epidemic diseases gives not only interesting, but even startling results. Compare it with cholera, for example, or typhus fever, or various other of this class of diseases. If I should say that it was a part of these diseases, in fact, the foundation upon which are constructed, it would seem strange, no doubt, to some, and even sibly be looked upon as being an ab statement, but it is nevertheless t Place them side by side and compare t symptoms. Nine-tenths of them are i tically the same—exactly coincide. same chronological order may not alw be observed in this comparison, neither is it always adhered to in symptoms of one case of a disease compared with other cases of the s disease.

The study of influenza by itself is v interesting, but when we compare it w other diseases and find it dominat them to the extent of nine-tenths of th symptomatic phenomena, it takes v definite shape as offering a clear, unm takable guide to the solution of th mysteries.

Taking a broad, bird's-eye view of field of epidemic diseases, it is impossi to avoid the conclusion, judging from intimate associations that they have w each other, and the absolute identity certain symptoms that are common them all, that they start from one comm center, and that, proceeding from t center, which, to all intents and purpo can be considered the simplest form which epidemic disease manifests its it passes through all gradations of cha down to the most complex forms of ease.

Naturally, when we compare th diseases together and find the princi symptoms of one disease running throu many of the others, if, in fact, not all behooves us to consider with extrem great care that one disease with a v to discover what relationship there m be existing between it and the others.

By a process of elimination, stripp the various epidemic diseases of th distinguishing marks in the shape symptoms that individualize one from other, we arrive at the bed-rock foun tion symptoms that seem common to th all, and these symptoms constitute disease known to us as influenza.

Now, realizing the fact that we compelled in this process of eliminat to progress through most complex fo

of disease before we arrive at these foundation symptoms, we are privileged to infer that having arrived there we have come to the simplest form under which epidemic disease manifests itself.

Proof that in influenza is to be found this simplest form of epidemic disease is furnished by a careful study of it in all of its phases. A mere superficial study of it is worse than useless. One had better leave the subject entirely alone if not prepared to thoroughly master it. Then, having mastered it, it is necessary to compare the disease with the other epidemic diseases, one by one, with the result that it will be found to furnish the key to a thorough knowledge of their etiology, a complete insight into their pathology, and naturally be of immense value to us from a therapeutic standpoint.

In the first place, influenza is essentially a disease of the mucous membranes.

Now, here we have a *constitutional* disease showing its effects upon the mucous membranes, alone, as a general rule, as acknowledged by all authorities upon the subject, notwithstanding the fact that the poisonous material causing it permeates the entire body.

But it is not confined to the mucous membranes, as is well known to any one having a wide experience with the disease, although this is its usual custom of localization in the simplest forms.

Now, it can readily be seen that if the amount of poisonous material absorbed is very slight, the effects will correspond and we will naturally have only perhaps a slight coryza, a little cephalalgia, etc. But if the amount be great the symptoms will take on more or less complex developments. Thus, the mucous membrane of the stomach and intestines becomes involved, the bronchial mucous membrane, as likewise the air cells, become affected, and so on through the different tissues and structures of the body, with consequent impairment of function of the different organs.

Upon the *amount* of material of a poisonous nature absorbed, as likewise the *degree of concentration* of that material in the system, will depend the simplicity or the complexity of the disturbances developed, and consequently, also, the simple or complex nature of the symptoms.

It can, in fact, run the gamut from the simplest of affections to the deadliest, just as syphilis can exhibit every shade of development, from a simple roseola to necrosis of bones.

Just here we come to a most interesting state of affairs. Instead of calling these complex disturbances that arise from time to time in the course of influenza as developments of the disease-process itself, they have been hitherto called "complications," an entirely misleading term.

The writer has referred from time to time in various papers to the indiscriminate use of this term. We might just as well speak of a syphilitic iritis as a "complication" of syphilis, a tubercular meningitis as a "complication" of tuberculosis, a scrofulous periostitis as a "complication" of scrofula, etc., etc.

The trouble and confusion arising from this misuse of the word in influenza, cholera, typhus, etc., is inconceivably great, and not only obscures from us a clear view of the essentials of disease, but also clearly indicates that the writers failed to recognize sufficiently fully the constitutional nature of these diseases. It should be sufficiently easy to understand that wherever the blood circulates, surcharged as it must be with the disease-producing material, anywhere in the economy, or, in fact, for that matter, everywhere, certain developments of disease must be anticipated.

Naturally, these metamorphoses must be expected at times to be very great. The whole aspect of the disease may be changed. Any part of the body being apt to become affected, it is certainly clear that, instead of regarding the localizations as "complications," we must regard them as part and parcel of the disease, no matter in what extremely severe form they make their appearances.

The disease, in its mildest forms, in other words, where it is only *skin deep*, as it were, meaning by this the cases wherein the mucous membranes alone are affected, can be looked upon with perfect justification, I think, as the "initial lesion" of the great epidemic diseases.

Where the disease goes deeper than the mucous membranes, involving the struc-

tures of different organs, as likewise becoming more diffused throughout the organism and consequently more severe and deadly, we can but regard these manifestations as secondary, tertiary, quaternary, quinternary, etc., forms of the disease, and *not as new diseases.*

Simply because one or two symptoms in some epidemics are of especially great prominence, and the pathological conditions underlying these symptoms are of especially pronounced and serious character, do not justify us in ignoring the fact that the vast majority of symptoms in the case are identically the same, nor blind us to the fact that these symptoms form the basic groundwork and foundation upon which all the epidemic diseases are constructed. Splitting hairs over the color of a few spots, or over the different waves of temperature, or over other details in the symptoms, easily recognizable to be in an absolute minority and completely ignoring the extraordinarily important fact that the vast majority of symptoms coincide, appear to me entirely unscientific methods of procedure. If we were to apply the same method of investigation to the widely-divergent manifestations of syphilis, we would have a score of diseases to mystify us instead of one. The "complications" which mark the different forms under which syphilis manifests itself are so numerous that it is only by a system of comparison, a putting of this and that together, that we are able to make a positive diagnosis in thousands of cases.

Now, applying the same method of investigation to the great constitutional diseases that go by the name of epidemic diseases, we readily find that the simplest form of them is found under the group of symptoms that characterize influenza. Should any one consider this doubtful let him parallel the various symptoms common to the different epidemic diseases. He will find nine-tenths of them identical with the symptoms that go to make up the disease known as influenza. Not always, as stated before, in the same chronological order. This would be too much to expect. In this it would not differ from the other constitutional diseases that are not known as epidemic diseases.

For instance, tuberculosis of bone is sometimes the first manifestation we have of the presence of tuberculosis. Inste of commencing at its simplest form takes on its gravest and most compl changes from the very beginning. T same might be said of syphilis, scrofu scorbutus, etc. If this is true of the *n epidemic* constitutional diseases, it shou also hold true of the *epidemic* consti tional diseases.

We should expect to find in this ca the severest symptoms exhibited first many epidemics, the chronological ord of procedure being entirely reversed, a patients carried off by thousands fro the fierceness of the attack, without ha ing had the opportunity of going throu the primary or milder forms of the d ease.

In a recent paper (MEDICAL BRIEF, Ja uary, 1907, page 66) I quoted from Pro Lebert, showing that where patients r cover from the fierce onslaught of a attack of cholera they pass through wh is known as the stage of reaction, which stage the symptoms are *identic* with the symptoms of influenza!

When we recall the fact that a profu diarrhea is one of the commonest wa in which an attack of influenza is term nated, and bearing in mind the severit at times, of the gastric and intestina symptoms in many of the epidemics o influenza, it seems impossible to escap the conclusion that upon the degree o potency of the poisonous material ab sorbed by the system, as well as th amount of it exhibited, will depen whether the disease takes on a primar or simple form from the beginning an be comparatively slight, or, on the othe hand, brushing aside the formalities o an attack in the usual order, makes it appearance in a secondary, tertiary quaternary, quinternary, etc., form, th severity of the case and its degree o complexity depending upon the organ involved, etc.

Naturally, and properly, our medica nomenclature must expand according a the various developments of epidemic dis ease occur, but to label every combinatio as it arises with a cognomen that would lead one to think he was dealing with an entirely new disease, simply obscures our perception of the essentials of disease,

and naturally leads us far from the right path in our investigations.

The idea of isolating each group of symptoms, each new combination of pathological happenings as they develop, and losing sight of the fact that nine-tenths of the phenomena making up these different combinations are almost exactly identical, and then placing these isolated groups in separated niches, like so many sculptured statues, labeling them, *e. g.*, red fever, green fever, blue fever, yellow fever, etc., is about as absurd as it is unscientific.

Confining our investigations to the different diseases separately, without comparing them together, and paralleling the symptoms that are common to them all, is an extremely unsatisfactory method of procedure, and leads to no definite scientific elucidation of the mysteries of the epidemic diseases.

On the other hand, taking a broad-minded view of the whole subject, putting this and that together, as one of our great detective sleuths in an important case laid before him would do, leaving not the slightest shred of evidence uninvestigated, we would, by comparing one disease with the others, etc., taking also into account the known facts with regard to them as handed down to us from medieval and ancient philosophers, and not ignoring these facts, as is done at the present time, we would be surprised and gratified at the results.

Some of these facts have to do with meteorological phenomena, that have from time immemorial been so closely interwoven with the epidemic diseases that a study of these diseases without a study of their connection with these phenomena amounts to the same as a study of "Hamlet" with that gentleman left out.

The absurdity of ignoring these phenomena ought to be patent to all, when we reflect that the very periodicity of our epidemics is proof positive of the connection of them with the earth's course through space, and with the chemical and electro-chemical activities encountered.

The every-day medical man may think that, in discussing the causes of disease, we can readily dispense with meteorological phenomena; in fact, leave this phase of the subject resting quietly in the graves of the ancients, together with their superstitious views concerning the influence exerted by the planets, etc., upon the earth, causing plagues, famines, etc. But if he could reflect for an instant upon the fact that the human body is a complex chemical substance, with chemical and electro-chemical activities in operation constantly, these activities continued in their functions by extrinsic chemical substances, such as the food we eat, the water we drink, etc., and then consider that these so-called meteorological phenomena are nothing more nor less than chemical and electro-chemical operations in progress, with the human body as one of the objective points of attack in the universal process of disintegration transpiring, he ought certainly to see that it is absolutely imperative upon us to study carefully these phenomena, *i. e.*, these chemical and electro-chemical activities, with a view to determine, if possible, whether or not our epidemic diseases are not directly traceable to them.

The periodicity of our epidemics, the known coincidental occurrences of meteorological activities with these diseases, the fact that the body is a complex chemical substance, and incapable, according to all acknowledged chemical laws, of escape from surrounding chemical, etc., environments, makes it impossible to avoid the conclusion that one of the main factors, if, indeed, not the principal one, in producing these diseases, is to be found in these meteorological so-called phenomena, which are nothing more nor less than purely chemical processes.

The greatest enlightenment upon the subject of epidemic diseases can only come by studying them, not only individually but collectively, comparing one with another; then, taking into account the varying conditions of climate encountered throughout the different latitudes, calculate carefully the changes that must ensue in these affections, according as the nature of the exhalations of soil, flora, etc., pertaining to the different localities varies; and, finally, not content with restricting our observations to the earth alone, it is of the highest importance to consider the extra-terrestrial chemical and electro-chemical activities that form indisputably

the connecting link with the periodic returns of these diseases, this periodicity being due unmistakably to the career of the earth through space. Else to what is this periodicity, more or less irregular though it be, due? Is it to be quietly ignored simply because the problem of solving it is too difficult?

A broader-minded consideration of the whole subject of epidemic disease than that furnished by the eye-piece of the microscope is absolutely essential to solving this problem of periodicity, as well as the various other problems that have hitherto baffled ancient and modern investigators.

[Written for the MEDICAL BRIEF.]

Headaches—Cause, Relief, Cure—A Few Suggestions.

BY E. W. CAPEN, M. D.,
Monson, Mass.

No enforcement of pure food laws is necessary to convince the careful observer that to have as our only armament against the various headaches a tablet of some coal-tar sedative, is a very poor recourse, and bound to become more and more unsatisfactory as time goes on. No headaches from mere perversity, though it may be granted if you wish that perversity has made many a headache. From this, then, you infer that once the cause is ascertained the effect may be made to cease. One kind of headache comes in one place on the head; another cause produces an entirely different "achy" spot. Among the more prominent causes of headache may be mentioned anemia, hyperemia, reflex causes, rheumatism, toxic and catarrhal.

Anemia is a very frequent cause of headache, and quite commonly affects girls at puberty. Depression and lowness of spirits with periods of extreme timidity characterize the state, and usually there is pallor, and sometimes palpitation. The location of the pain is variable, being sometimes in the vertex and sometimes in the forehead and temples; more rarely the occiput. The pain is of a dull, gnawing kind, and more constant than severe. Dizziness and fainting are not u common.

Relief and cure depend on the resto tion to normal of a depleted blood. Su shine, fresh air, good, nourishing, abu dant and easily digested food, and, if pos ble, a change of environment, beside t medicinal treatment, will speed and mak permanent the cure. Iron, manganes arsenic, quinine or strychnine may called for medicinally, and in chlorot girls the addition of pulsatilla is of ine timable benefit. Blaud's pills have yet t be bettered as a method of administerin iron.

Hyperemic headache may be due to e cessive mental application. The bloo vessels are engorged, ideas flow wit great profusion, or there is a torpor, d pending whether the engorgement is art rial or venous. There may be illusion and the face is flushed, the carotids pul sate violently, the eyes are suffused, an the whole picture is one of extreme con gestion. Pain, sometimes intense. Rest light diet; very small allowance of meat and that not red; no alcoholics; frequen bathing and a liberal allowance of physi cal labor counteract this condition. Bella donna is the drug most often indicated A course of salines is good accessory treatment.

Reflex headache may tax the utmost ingenuity of the physician. First, to locate the cause and then to correctly treat it. A wonderfully complicated nervous system may add to the efficiency and variety of human accomplishment, but that it also adds to the difficulty of locating the seat of many an ailment is the daily experience of thousands of astute physicians. Bilious headaches, uterine headaches, indigestion headaches, headache from eye-strain, headache from any one of manifold other causes, dependent for inception on some impressionistic condition of the nervous system coupled with a more or less acutely deranged organ, serve to emphasize the fact that what might be a very simple thing often is a very complex one.

Headaches referable to stomach and sexual organs are likely to appear at the base of the skull; also those due to rheumatism, at times. The sides of the head ache from troubles in the small intestine;

the forehead from large intestine or loaded colon or rectum; below or under the superciliary ridges from catarrhal conditions; the vertex from uterine or vesical complications; the occiput from muscular eye-strain. Neurasthenic headache may appear at any place, and neuralgic also, and any two may be combined and present a picture that is far from easily interpreted. If a headache seems to refer to a particular organ, assure yourself that this organ is really the offender by finding its deranged function before treating it. So, and only so, can proper treatment be instituted.

For digestive headaches a good active cathartic, then a bitter tonic, as strychnia, or the crude nux vomica, with pepsin, and, perhaps, pancreatin for temporary relief. For bilious or sick headaches, a good liver stimulant, as chionanthus, sanguinaria, chelidonium, or even calomel, coupled with a regular laxative as the compound aloin pill.

For eye-strain, rest and glasses.

For uterine, proper local treatment and helonias, pulsatilla, aletris, actea racemosa, or other special drug.

For catarrhal conditions, antiseptic sprays and a mucous membrane tonic. internally, as hydrastis or the iodide of arsenic in one one-hundredth grain doses.

For bladder troubles, hexamethylene, tetramine, and plenty of water.

For all, careful diet, free exercise, fresh air and rest.

Rheumatic headache affects chiefly the scalp, and has a heavy, continuous pain, with tenderness. It is worse toward evening and before a storm.

Treated by general rheumatic remedies, a vegetable diet; no liquors; full indulgence in water, especially lithia water, milk, and keeping the feet dry and warm. Rhus toxicodendron, bryonia, sodium salicylate, colchicine, iodide of potash and numerous other drugs recommended show that there is no specific.

Toxic headaches are from absorption or non-excretion. Alcoholic, narcotic, uremic or malarial are the common forms of the poison. Free catharsis for the first two, with apomorphia for the first and strychnia for the second will be found very useful. Malarial should be treated with quinine. Uremic by lessening the ingestion of meat; lessening exercise; increasing perspiration, free catharsis and diuresis.

With catarrhal conditions in addition to previously mentioned treatment, all foreign growths as adenoids, spurs, and the like, should be removed; a dry climate may be sought; good elimination should be obtained, and care taken to prevent wet feet and exposure to draug..

Nothing is so common to the physician as headaches; few things so annoying, and for the increasing one's clientele of grateful patients nothing so potent as the cure of headache.

A Just Appeal.

DEAR SIR—I have for many years been a subscriber to your helpful and progressive medical journal. I now appeal to you on behalf of myself and family, who have been rendered shelterless and penniless in consequence of the terrible earthquake here on the fourteenth of January, causing the loss of fully one thousand lives. As all my savings were invested in house properties, and these are all demolished, I am now financially ruined, after many years of hard toil. I earnestly request you to do your very best to obtain such assistance from the members of the BRIEF family, and from any other kind and generous persons to enable me to rebuild my home, and may Almighty God, the great Architect Divine, the more abundantly bless each donor, and preserve them from a like calamity.

Sincerely,

C. H. BARRINGTON ARMSTRONG, M. D.

[All members of the profession who desire to help the doctor can address him at 38 East street, Kingston, Jamaica.—ED.]

Consolidation of Medical Journals.

We are pleased to note the fact that the old and well-known *Medical Mirror*, which was conducted by the lamented Dr. I. N. Love, has been consolidated with the *Medical Era*, and will be known in the future as the *Medical Era*. We wish the *Era* success in its acquired efforts.

Examination Questions and Answers Maryland Examining Board, June 20-23, 1906.

ANATOMY.

1. Describe the upper extremity of the femur.

ANSWER.—It comprises a head, neck, greater trochanter, and lesser trochanter. The head, directed upward, inward, and forward, is hemispherical and coated with cartilage. It articulates with the acetabulum, and presents a small fossa at about the center of the articular surface for the ligamentum teres. The neck is a strong bar serving to join the head to the shaft at an angle of approximately 125 degrees. Its vertical diameter is greater than its thickness, and it is widest where it joins the shaft. Its junction with the shaft is marked anteriorly by a ridge which terminates above in the tubercle. Posteriorly the intertrochanteric ridge crosses the widest part of the neck. In front of the upper part of this line is the digital fossa. The trochanter major is a large cuboid process surmounting the shaft so as to overhang the digital fossa. Its outer surface is rounded and presents an oblique line passing from the upper back angle to the lower front angle. This process presents also an oblong anterior surface, a superior border, and a posterior border; the latter being the upper part of the intertrochanteric ridge. The trochanter minor is a prominent process situated at the back of the shaft about two and a half inches below the greater trochanter.

2. Describe briefly the elbow joint.

ANSWER.—The elbow joint is a typical hinge joint. The bony formation of the joint consists in the trochlea, of the humerus lying in the grasp of the sigmoid cavity of the ulna, together with the capitellum of the humerus resting in the cup on the head of the radius. The ligaments, as a whole, form a capsule, enveloping the joint, but studied separately they are: (1) The anterior ligament, lying in front and attached mainly above to the margin of the coronoid fossa and below to the margins of the coronoid process and orbicular ligament. (2) The posterior ligament is thin, passing from the upper margin of the olecranon fossa downward to the olecranon. (3) The internal lateral ligament, fan-shaped, is attached by its upper narrow end to the internal condyle and by its lower broad end to the inner edge of the sigmoid cavity. (4) The external lateral ligament passes from the external condyle above downward to the orbicular ligament below. The synovial membrane lines the inside of the capsule and is reflected onto the articular surfaces. A pad of fat occupies the coronoid fossa and the olecranum fossa.

3. Name the accessory sinuses of the nose.

ANSWER.—(1) Maxillary, (2) Frontal, (3) Sphenoidal, (4) Ethmoidal, (5) Palatal.

4. Describe the collateral circulation after a ligation of the internal iliac artery.

ANSWER.—"By the anastomoses of the uterine and ovarian arteries (in the female); of the opposite vesical arteries; of the hemorrhoidal branches of the internal iliac with those from the inferior mesenteric; of the obtura artery; by means of its pubic branch, with the vessel of the opposite side and with the epigastric and internal circumflex; of the circumflex and perforating branches of the profunda femoris with the sciatic; of the gluteal with the posterior branches of the sacral arteries; of the ilio-lumbar with the last lumbar; of the lateral sacral with the middle sacral; and of the circumflex-iliac with the ilio-lumbar and gluteal."—Gray.

5. Name and give location of the salivary glands and state just where their ducts empty.

ANSWER.—The parotid glands are situated just behind the rami of the lower jaw, and their ducts (Stenson's) empty into the mouth opposite the second upper molar teeth. The sub-maxillary glands lie in the sub-maxillary triangles under cover of the angles of the jaw, and their ducts (Wharton's) open into the floor of the mouth on each side of the frenum of the tongue. The sub-lingual glands lie on the inner surface of the mandible just above the milohyod ridges, and their ducts, several in number (ducts of Rivinus), open through the mucous membrane covering the glands.

6. Describe the portal system of veins.

ANSWER.—"The portal vein conveys blood from the stomach, from the whole of the intestine, except the terminal portion of the rectum, and from the spleen and pancreas to the liver. Unlike other veins, it ends like an artery by breaking up into branches, which ultimately terminate in capillaries in the substance of the liver; from these portal capillaries the hepatic veins, which also receive the blood conveyed to the liver by the hepatic artery, arise; and as these open into the inferior vena cava, the portal blood ultimately reaches the general systemic circulation."—Cunningham.

OBSTETRICS AND GYNECOLOGY.

1. Describe the preliminary arrangements and preparation for an approaching accouchement.

ANSWER.—Clean, well heated, lighted, and ventilated room free from all dust, superfluous furniture and hangings, with a narrow bed or cot for confinement prepared with rubber sheet and draw sheet. Two pitchers for hot and cold sterile water with three basins for washing and holding solutions should be present, also douche pan, three dozen sterile pads, three binders for mother and clothes for baby. At beginning of labor patient should have general bath, especial care being given the genitals, and an enema. On near approach of delivery put to bed on Kelley pad or extra rubber sheet, wash genital region with soap water and antiseptics and clip hair. Cover surrounding regions with sterile towels.

2. What is your treatment for a case of placenta previa about the eighth month of pregnancy?

ANSWER.—If no hemorrhage is present and patient accessible, await onset of labor. Where there is hemorrhage or labor has begun, dilate and apply forceps or do a podalic version and bring down thighs as a plug, according to indications of individual case. If neither of these

can be done vagina may be tightly filled with gauze and allow presenting part to push it out.

3. Give diagnosis of a pregnancy at the third month.

ANSWER.—At this period absolute diagnosis is difficult or impossible. Symptoms are cessation of menstruation, nausea and vomiting, tingling in breasts, symptoms of pressure on bladder and rectum, nervous disturbances. Physical signs are softening and increase in size of cervix lower uterine segment and whole uterus which is fig shape and at top of symphisis; increased pigment in face, breasts, abdomen and vagina, increased vaginal secretion and size of breasts. From cancer or other tumor by history, consistency of uterus, lack of menstruation.

4. Describe the mechanism of a podalic version and mention the points of danger to the fetus.

ANSWER.—Pass the hand corresponding to the child's face into the uterus and grasp one or both feet, usually the anterior. Pull down on it and at the same time push the buttocks from opposite side or the head upward with the free hand. Child may receive some injury, like fracture, from hand in utero, may be asphyxiated by pressure on cord in delivering after coming head, or have neck or other bones fractured in so doing.

5. Describe a complete abdominal hysterectomy.

ANSWER.—After sterilizing hands, instruments and abdomen and anesthetizing patient, open abdomen in median line just above pubis by incising down to peritoneum and then raising and cutting peritoneum so as to avoid intestines. Ligate the ovarian arteries and place clamp on proximal sides of ligatures, cut between them, going down through broad ligaments nearly to uterine arteries. Incise peritoneum on anterior surface above bladder and push bladder off with gauze, ligate uterine arteries ¼ to ½ inch from cervix so as to avoid ureters, carry broad ligament incision to vault of vagina proximal to ligatures. Cut around vaginal vault at junction with uterus and remove; stitch edges of vagina together or leave partly open if drainage is indicated. Stitch together edges of broad ligaments and peritoneum from bladder and pouch of Douglas. Mop peritoneum free from blood. Close wound with layer sutures, leaving in normal saline sutures.

6. Describe some conditions of the uterus which may be relieved by an amputation of the cervix.

ANSWER.—Conditions of the cervix most helped by an amputation are great hypertrophy and elongation, especially where stenosed, and a much lacerated one full of cicatricial tissue and much congested or where cysts or chronic infection exist confined to cervix. Operation not sufficiently radical for malignancy.

PRACTICE.

1. Define: (a) Tachycardia, (b) Leukemia, (c) Cretinism, (d) Hydrothorax, (e) Ascaris Lumbricoides.

ANSWER.—(a) Tachycardia (pulsus frequens) is an increased frequency in pulse rate, and may be constant or paroxysmal, physiologic or pathologic. (b) Leukemia is a disease characterized by a marked increase in the number of leukocytes in the blood, together with the enlargement and proliferation of the lymphoid tissue of the spleen, lymphatic glands and bone matter. Anemia, internal hemorrhage and increasing exhaustion are constant symptoms. (c) Cretinism is a congenital condition associated with absence or disease of the thyroid gland, and characterized by premature ossification of bones with deformity of head and face, stunted growth, mental dullness or idiocy. (d) Hydrothorax is an effusion of fluid in the pleural cavities. (e) Ascaris Lumbricoides is a common intestinal parasite inhabiting the small intestines and is generally known as the round worm.

2. Name symptoms of: (a) Ulcer of the Stomach, (b) Acute Nephritis, (c) Scarlatina.

ANSWER.—In ulcer of the stomach there are various manifestations of indigestion. Paroxysmal pain localized in the pit of the stomach, or radiating from this point to limbs and back; aggravated by the taking of food, especially very hot, cold or spicy articles. Gnawing pain may be present between attacks of gastralgia. Localized tenderness (Boas's point) is very constant, and is elicited, usually, from one to two inches above pylorus. Vomiting is common, and if immediate, indicates ulcer near cardiac orifice. Pyloric ulcer gives rise to vomiting about one hour later. The vomitus contains undigested food and mucus, and is hyper-acid. In hematemesis, which occurs in about forty per cent of cases, the vomitus contains bright red blood or clots. The passage into intestines shows as dark stools. Enlargement in region of pylorus is infrequently demonstrated. Analysis of stomach contents shows increase in hydrochloric acid. Anorexia, anemia, loss of weight and strength are invariably present. (b) Acute Nephritis. The onset is rarely by a chill, but usually sudden, and characterized by dyspnea, sometimes by nausea and persistent vomiting. Fever is variable, ordinarily moderate. A full and tense pulse. Dull pain is experienced over kidneys, posteriorly, rarely referred along ureters. The desire to urinate is frequent, and the skin is harsh and dry. Dropsy appears early, and is first noticed in face and eyelids, ranging from a puffiness to general anasarca. Uremic symptoms may be added at any time; anemia and weakness develops early. Urinary symptoms are most characteristic. The urine is scanty, smoky, and of high specific gravity. Albumen is present in large quantities. The urea excreted is greatly lessened, as are also the phosphates and chlorides. Microscopically is found hyaline, blood, granular and epithelial casts. Uric acid, urates and oxyalate crystals. Blood corpuscles and epithelium. (c) (Ordinary type) Period of incubation varies; usually about four days. Begins abruptly, as a rule, rarely by a chill. Commonly vomiting, with convulsions in young. Fever rises rapidly, reaching 104° F. or 105° F. first day. Pulse range unduly rapid, one

hundred and ten to one hundred and fifty. Pain in the throat and difficult swallowing. Bright scarlet rash appears at the end of twenty-four hours, visible first on neck and chest, spreads over body in course of several hours. The rash is uniform, not elevated, and disappears on pressure and there is no intervening healthy skin. Average duration of rash is from three to four days, and slowly disappears. Strawberry tongue is characteristic. Nervous symptoms mitigate or disappear when rash is established, and the temperature declines by lysis, reaching normal about the seventh day. Desquamation as scales and flakes begins at this period, and is rarely complete before the fifth week. Scanty albuminous urine is not uncommon. Intestinal symptoms not prominent.

3. What means would you employ in the diagnosis of diseases of the lungs, stomach, and kidneys?

ANSWER.—In diagnosing conditions of each, obtain a comprehensive history of the patient, including the family, his past and present. And in diseases of the lungs, employ inspection, palpation, percussion, auscultation, mensuration and succussion. If obtainable, examine microscopically and macroscopically sputa and exudates. In examinations of the stomach employ inspection, palpation, percussion, auscultation and succussion. Inflate and determine size and position of organ. Administer test meal and examine contents of stomach. Ascertain the motor and absorptive power and examine bacteriologically. In diagnosing kidney disease, employ inspection, palpation, percussion and auscultation. Secure specimen by catheterism of bladder of ureters, if necessary, and examine. Determine twenty-four hours quantity, color, odor, consistency, specific gravity, reaction, total urinary solids; examine for albumen, sugar, blood, bile-pigment (sudican), acetone, diascetic acid, oxybutyric acid, fat and pus. Microscopically for cast, organisms, etc.; also verify certain substances found macroscopically and chemically.

4. Name some of the sequels of typhoid fever. Name some causes of intestinal obstruction.

ANSWER.—The sequelæ of typhoid fever are manifold, as, persistent diarrhea, lobar pneumonia, bronchitis, pleuritis, ulceration of larynx and laryngeal paralysis, endo and pericarditis, thrombosis of veins, gangrene of foot and legs, pharyngitis, suppurative prostitis, cholecystitis, gall stones, neuritis, post typhoid insanity, paralysis, arthritis, nephritis, conjunctivitis, otitis, decubitis, bone necrosis and various skin lesions. Briefly stated, the causes of intestinal obstruction are strangulation, intussusception, volvulus, fecal impaction, enteroliths, gall stones, tumors, strictures, intestinal paralysis and abnormal contents.

5. Give treatment of diabetes mellitus and of laryngeal diphtheria.

ANSWER.—Interdict or reduce to minimum the starches and sugars. Allow non-carbohydrates. Use saccharin or glycerine in lieu of sugar when latter is demanded. Ventilation, fresh air, daily bathing, appropriate exercise and attention to secretions are essential. Fatigue and exposure avoid. Medicinal treatment is unsatisfactory, as no drugs recommended have a direct curative influence. Opium is a remedy capable of limiting the progress of the disease. It should be given in increasing doses until sugar is reduced to a minimum, and then gradually withdrawn. Next to opium codeine probably deserves the most confidence. Many drugs, such as bromide of arsenic, the salicylates, nitroglycerine, potassium iodide, lactic acid, adrenalin. Fair doses of the coal tar products, notably anti-pyrine and the preparations of the pancreas are recommended. Chloral and the bromides are useful adjuncts, and benefit nervous symptoms. The various skin lesions should receive appropriate treatment. Coma is an almost hopeless complication, and requires inhalation of oxygen, hypodermoclysis and interoclysis, alkalies are esteemed as preventives. Stimulate. (b) When the larynx becomes involved in a case of ordinary diphtheria, the following additional measures are advisable. A steam tent may be arranged so that the patient may breathe an atmosphere saturated with moisture. The vapor of slaking lime, and lime water with glycerine is a suitable remedy. If dyspepsia becomes urgent, prompt acting emetics should be administered. When suffocation is threatened from the laryngeal obstruction, intubation or tracheotomy should be immediately performed. Antitoxin should be given heroically. Bold stimulation.

6. Give diagnosis and treatment of tetanus.

ANSWER.—Trauma or wound antedate the onset. Infrequently begins abruptly, commonly by headache and chilliness with stiffness of the neck. Tonic spasm of the masseters (lock-jaw) develops early. Head is drawn back and legs extended, and the body is thrown into general spasm. The arms, however, are little involved. Spasms are excessively painful, and recur spontaneously, and result from external irritants. The muscles remain tonically contracted during intervals. Febrile reaction is variable. *Treatment*—It is imperative that the patient be confined to bed in a quiet, darkened room. Scrupulously prohibit all source of irritation and excitement. Incise and antisepticize the wound. The spasms will require the inhalation of chloroform or nitrite of amyl, and the administration of such drugs as chloral, morphine, codeine, bromide of potash, antipyrine, belladonna, etc. Use antitoxin of tetanus. Maintain nutrition by rectal alimentation, or feed through nose with catheter. Liberal stimulation when advisable.—*State Board Journal of America.*

Book Notices.

INDICATIONS FOR OPERATIONS IN DISEASES OF THE INTERNAL ORGANS. By Professor Hermann Schlesinger, M. D., Extraordinary Professor of Medicine in the University of Vienna. Authorized English translation by Keith W. Monsarrat, M. B., F. R. C. S. (Edin.), Surgeon to the Northern Hospital, Liverpool. New York: E. B. Treat & Co. Price, $3.00.

When diseases of the internal organs have gone beyond the control of drugs, and operations for relief are necessary, it is well to have a guide along the suggestions as to how best to relieve the conditions. This work has been specially written to aid the general practitioner as to when surgical intervention is proper. This work is based on the views arrived at by private practice of the author in many years' work in hospital and private practice, and has given him the opportunity of acquiring a large experience in the questions which are discussed in this work. There should be some advantage in the circumstance that a physician who is in full sympathy with the standpoint of the surgeon here presents to the practitioner a discussion of the question of surgical intervention. Do not fail to secure this work, as it will do you good.

GENITO-URINARY DISEASES AND SYPHILIS. By Henry H. Morton, M. D., Clinical Professor of Genito-Urinary Diseases in the Long Island College Hospital; Genito-Urinary Surgeon to the Long Island and Kings County Hospitals, and the Polhemus Memorial Clinic. Illustrated. Second edition, revised and enlarged. Philadelphia: F. A. Davis Co., publishers. Price, $4.00.

Genito-urinary surgery is surely on the increase in regard to methods, and any work that shows the spirit of progressive ideas should be recognized. It was found necessary in this volume to make changes in regard to advanced methods, therefore it was found necessary to change some of these in surgical operations, especially in regard to prostatic hypertrophy and a more thorough understanding of its pathological anatomy. The inflammatory affections of the prostate have been also more fully studied, and the knowledge of the surgical diseases of the kidney in regard to both diagnosis and treatment have both been considerably increased. It is a good subject to read, and the author gives good food for a digestion of thought on the things that may arise to the general practitioner. It should be read by the specialist and general practitioner.

OCULAR TEST CHART. By George Mayerle, San Francisco, Cal. The Result of Many Years of Theoretical Study and Practical Experience, of Great Interest to the Medical Profession Throughout the World. San Francisco: George Mayerle, Publisher and Author. Price, Distant Chart, with Cabinet, $6.00; without Cabinet, $3.00; New Reading Test Card, $1.50. For full information see advertisement on our pages.

This chart will increase the physician's income, owing to the fact that so many cases come to the family physician when no specialist is near at hand, and he will find that it eliminates the great danger of mistakes, and convinces the patient as to his professional skill and ability to diagnose, and, at least, correct defective eyesight. We have never seen anything that equalled this chart for the use of the general practitioner. It would be well for all our friends to fully consider this proposition.

A TEXT-BOOK OF CLINICAL DIAGNOSIS. By Laboratory Methods. For the Use of Students, Practitioners and Laboratory Workers. By L. Napoleon Boston, A. M., M. D., Associate in Medicine and Director of the Clinical Laboratories Medico-Chirurgical College, Philadelphia; formerly Bacteriologist at the Philadelphia Hospital and at the Ayer Clinical Laboratory of the Pennsylvania Hospital. Second edition, revised and enlarged, with three hundred and thirty illustrations. Philadelphia and London: W. B. Saunders & Co. Price, cloth, $4.00; sheep, $5.00.

In a clinical diagnosis it is well to be thorough, therefore to examine carefully the sputum, feces, blood, etc., is of great importance, and every physician, to be successful, should have a thorough knowledge of the significance of the chemic and microscopic findings in the laboratory, as this is found to be absolutely necessary in successful therapeusis. This work of Dr. Boston will furnish a complete guide to correct diagnosis along these lines. We find many subjects that are not included in other works along this line. In selecting a work on diagnosis it is profitable to get the best and most complete.

PATHOLOGY, General and Special. A Manual for Students and Practitioners. By John Stenhouse, M. A., B. Sc., Edin., M. B., Tor.; Formerly Demonstrator of Pathology University of Toronto, Toronto, Can.; and John Ferguson, M. A., M. D., Tor., Senior Physician Western Hospital, formerly Senior Demonstrator of Anatomy University of Toronto, Toronto, Can. Series of the Medical Epitomes, edited by Victor Cox Pedersen, A. M., M. D., Lecturer in Surgery at the New York Polyclinic Medical School and Hospital, etc. Illustrated with sixteen engravings and a colored plate. Philadelphia and New York: Lea Brothers & Co. Price, $1.00.

This volume brings near to completion the Medical Epitome Series, which is to comprise twenty-three manuals authoritatively covering the whole field of medical education. Twenty of the above are now ready and three more volumes will be issued shortly, one on Nose and Throat, one on Gynecology, and one on Hygiene. Together, these will make an elegant library.

A TEXT-BOOK OF PHYSIOLOGY, For Medical Students and Physicians. By William H. Howell, Ph. D., M. D., LL. D., Professor of Physiology in the Johns Hopkins University, Baltimore. Illustrated. Philadelphia and London: W. B. Saunders Company. Price, $4.00.

In reading a work of this nature, if it is intended for the student as well as practitioner, one would expect the subject matter and the illustrations to be educating, clear and concise. This work has all the merits that go to make up a thorough correlation on the subject of which it treats. It has features that a teacher might develop with profit and benefit to his class. In this work it may be said that to follow any special subject more in detail some references have been given, and these have been selected usually with the idea of citing those works which may contain a more or less discussion on the subject.

THE OPERATING ROOM AND THE PATIENT. By Russell S. Fowler, M. D., Surgeon to the German Hospital, Brooklyn, N. Y. Fully illustrated. Philadelphia and London: W. B. Saunders Company. Price, $2.00.

This book has special features that are not expressed in any other work that we have had the pleasure of reviewing. It is primarily intended for surgeons, nurses, internes, and all others whose duties are in the operating room. For students it shows explicit directions in the lines of operations in all its perfections, such as instruments needed, position of patient, and all the accessories; then the illustrations are educators. It is a good work for the surgeon, student and hospital assistant.

A TEXT-BOOK ON THE PRACTICE OF GYNECOLOGY. For Practitioners and Students. By William Easterly Ashton, M. D., LL.D., Fellow of the American Gynecological Society; Professor of Gynecology in the Medico-Chirurgical College and Gynecologist to the Medico-Chirurgical Hospital, Philadelphia; formerly Lecturer on Gynecology in the Jefferson Medical College, Philadelphia; one of the founders of the Congrés International de Gynécologie et Obstétrique; member of the American Medical Association, etc. With ten hundred and fifty-seven new line drawings illustrating the Text, by John V. Alteneder. Third edition, revised and enlarged. Philadelphia and London: W. B. Saunders Co. Price, $6.50.

In one year's time this work has secured the distinction of a third revised edition. An author and a publisher can but feel gratified at such evidence of worth—to be seen and read is sufficient to guarantee its sale. There are many works on gynecology and it will be the survival of the best. This work has many features to commend it to both practitioners and students.

ESSENTIALS OF PRESCRIPTION WRITING. By Bernard Fantus, M. D., Professor of Materia Medica and Therapeutics, College of Physicians and Surgeons of Chicago, the College of Medicine of the University of Illinois; also Professor of Materia Medica and Therapeutics Jenner Medical College of Chicago. Chicago: Chicago Medical Book Co. Price, $1.00.

There are but few colleges that give a systematic training in prescription writing; therefore, works such as the one before us are a necessary adjunct to a collegiate course. Instructions in Latin have been very much simplified and reduced to the lowest possible terms, while the formulas of the present have been rather elongated and complex, and we believe this will lead to confusion, yet a work of this nature may solve the problem and be a benefit to the physician and pharmacist.

SURGERY. Its Principles and Practice. By Various Authors. Edited by William Williams Keen, M. D., LL.D., Professor of the Principles of Surgery and of Clinical Surgery Jefferson Medical College, Philadelphia. Vol. I. Two hundred and sixty-one Text illustrations and seventeen colored plates. Philadelphia and London: W. B. Saunders Company. Price, per volume, cloth, $7.00; half morocco, $8.00.

This work will be completed in five volumes, and have the practical benefits of what sixty-six eminent surgeons know of the practice. Could any work be more complete in the knowledge of surgical facts, when a list of the contributors include such names as Abbe, Adami, Andrews, Armstrong, Bennett, Bevan, Bickham, Binnie, Bland-Sutton, Brewer, Cabot, Carson, Codman, Coley, Coplin, Crile, Cushing, Da Costa, Da Costa, Jr., Dench, Dercum, de Schweinitz, Edsall, Eisendrath, Estes, Finney, Fordyce, Frazier, Freeman, Gerrish, Gibbon, Gottstein, Hekteon, Horwitz, Kocher, Lennander, Lewis, Lovett, MacDonald, Martin, Matas, C. H. Mayo, W. J. Mayo, McCaw, Moynihan, Mumford, Monro, Murphy, Nichols, Ochsner, O'Reilly, Osler, Owen, Ransohoff, Rixey, Roberts, Robson, Rodman, E. A. Smith, Harmon Smith, Spiller, Van Hook, Warbasse, F. C. Wood, Woolsey, Young. When such men lend their aid to a work what comment could we make to further its prestige? We rest here and leave to our readers.

DIET IN HEALTH AND DISEASE. By Julius Friedenwald, M. D., Clinical Professor of Diseases of the Stomach in the College of Physicians and Surgeons, Baltimore; and John Ruhrah, M. D., Clinical Professor of Diseases of Children College of Physicians and Surgeons, Baltimore. Second edition, thoroughly revised and enlarged. Philadelphia and London: W. B. Saunders Co. Price, cloth, $4.00; half morocco, $5.00.

The preface to the present edition will more fully explain the worth of this work, so we quote: "The success of the first edition of this book seemed to indicate that it filled a need of the profession. In this second edition we have made numerous minor changes and additions which we trust will make the book more valuable. We have re-written and enlarged the section upon salts, noted the work of Chittenden, given a more extended account of Prochowinick's diet for pregnancy complicated by contracted pelvis, and have added an account of the diet at water cures, and of Klemperer's work on oxaluria. We have added a revised list of recipes and a new set of dietlists for ready reference at the end of the book." This should appeal to the profession as a work well worth the time and expenditure.

DISEASES OF THE DIGESTIVE SYSTEM. Edited by Frank Billings, M. D., Professor of Medicine University of Chicago, and Professor of Medicine and Dean of Faculty Rush Medical College. An authorized translation from "Die Deutsche Klinik," under the general editorial supervision of Julius L. Salinger, M. D., with forty-five illustrations in the Text. New York and London: D. Appleton & Co. Price, $4.50.

The advances of today have given the practitioner and student a better basis for diagnosis and treatment than they have ever had in the past. To keep up with these advanced ideas they are required to read up on authoritative works to show that while much in the past has been based on theoretical ideas, they have now almost become established facts. The study of metabolism has lifted the veil of mystery from much that was obscure. What is metabolism but the chemical changes occurring in nutritive material taken into an organism by which it is converted into an integral part of the living substance? The volume not only treats of these subjects, but a new study has been opened, or more properly revised, namely, the investigation of the feces. Many things have been added in this volume that is sure to commend it to all its readers.

GENITO-URINARY DISEASES AND SYPHILIS. Including their Surgery and Treatment. By Charles S. Hirsch, M. D., Assistant in the Genito-Urinary Surgical Department Jefferson Medical College Hospital. Illustrated. Philadelphia: P. Blakiston's Son & Co. Price, $1.00.

This is one of Blakiston's Quiz Compends. It will serve to facilitate the student in mastering the important points in the diagnosis and treatment of such complications as come to him in such disorders. It gives medicinal and surgical treatment, and such formula as found efficient in the best practitioners.

DISEASES OF THE STOMACH. A Text-Book for Practitioners and Students. By Max Einhorn, M. D., Professor of Clinical Medicine at the New York Post-Graduate Medical School and Hospital; Visiting Physician to the German Hospital. Fourth revised edition. New York: William Wood & Co. Price, $3.50.

It is an opportune time to study up on stomach troubles, owing to the great increase of this bane to the human economy. The views have changed in late years in regard to diagnosis and treatment; therefore, anything that leads to a solution of the best treatment is welcome. So many good things have been printed on the pages of the BRIEF that it would seem strange to read such works and not find the trend of practical original experiences by professors of note incorporated. There is no better author on this subject than Einhorn. Therefore, we endorse this work as the best.

THE PRACTICAL MEDICINE SERIES: Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the General Editorial Charge of Gustavus P. Head, M. D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School, Vol. VII. PEDIATRICS—Edited by Isaac A. Abt, M. D., Assistant Professor of Medicine (Pediatrics Department) Rush Medical college. ORTHOPEDIC SURGERY—Edited by John Ridlon, A. M., M. D., Professor of Orthopedic Surgery Northwestern University Medical School. With the collaboration of Gilbert L. Bailey, M. D., Instructor in Orthopedic Surgery, College of Physicians and Surgeons. Chicago: The Year Book Publishers. Price for the Series of Ten Volumes, $10.00. Price of this Volume, $1.25.

This series of year books makes a good acquisition to any library and can be secured complete for ten dollars, but should any specialist wish a separate volume he can secure it on payment of same at price stipulated. This volume is a good one on the diseases of children and orthopedics. If you are not a patron to this series you should be.

HUNDREDTH CENTURY PHILOSOPHY. By Charles Kirkland Wheeler. Boston: Press of James H. West Company. Price, $1.06.

This is a work on new thought, is an evolution, and can only be read by those who wish to leave the childhood ideas and seek advanced thoughts along the lines of an advancement of the race. The ideas expressed are very deep and need an active and cultured mind to grasp them, yet we believe it will result in good to read this work.

A SYLLABUS OF MATERIA MEDICA. Compiled by Warren Coleman, M. D., Professor of Clinical Medicine and Instructor in Materia Medica and Therapeutics in Cornell University Medical College; Assistant Visiting Physician to Bellevue Hospital. Third edition, revised to conform to the eighth decennial revision of the U. S. Pharmacopeia. New York: William Wood & Co. Price, $1.00.

Owing to the requirements of the State Boards it has been made necessary to conform to the plan of giving official preparations in the examinations. This necessitates a radical change from the former editions. The section formerly headed "Preparations" has been abolished, thus curtailing its usefulness to the liberal practitioner. There are many changes as well as some mistakes in this issue.

MODERN MATERIA MEDICA AND THERAPEUTICS. By A. A. Stevens, A. M., M. D., Professor of Therapeutics and Clinical Medicine Woman's Medical College of Pennsylvania; Lecturer on Physical Diagnosis in the University of Pennsylvania; Physician to the Episcopal Hospital and to St. Agnes's Hospital; Assistant Physician to the Philadelphia Hospital; Fellow of the College of Physicians of Philadelphia, etc. Fourth edition, thoroughly revised. In conformity with the eighth revision (1905) of the United States Pharmacopœia. Philadelphia and London: W. B. Saunder & Company. Price, $3.50.

This work was originally printed in 1894, and is now thoroughly revised to date, and in its fourth edition. That there is need for this work is evident by the present edition.

THORNTON'S POCKET MEDICAL FORMULARY. New (8th) edition, revised to accord with the new U. S. Pharmacopœia. Containing about two thousand prescriptions with indications for their use. In one leather bound volume. Philadelphia and New York: Lea Brothers & Co., publishers. Price, $1.50.

Thornton's Formulary has proven itself a very useful work to lend aid to the practitioner in the past, and now that it has been revised to conform with the latest methods and thus gives the changes that have been made since your old text-books were issued, owing to the changes made in the strength of drugs and their preparations, it would be well to secure this edition and thus make no mistakes.

Editorial.

Imitation Remedies.

No good doctor will use an imitation remedy. The so-called pharmaceutical remedies that have recently been recommended to replace standard ethpharmal proprietaries, are based on simply the smell and taste like originals, and not on merit, but to be cheap to bear large profits.

Better or Worse.

It is fashionable to say one druggist can put up a medicine as good as another. This is an absurdity. You might as well say one man can cook as well as another. We visited a hotel once and ate apple pie one day, and it was execrable. The next day the waiter brought on some apple pie that was simply delicious. We asked the waiter why it was, and he said the old cook was absent the day before, and they had a new man at the business.

Experts.

What is the use of medical expert testimony? If you will notice, the expert always testifies on the side that hires him, and for this reason his testimony is valueless.

Pasteurized Milk.

It has been asserted, probably with truth, that no baby could be raised to manhood on Pasteurized milk only.

No Discovery.

A doctor recently claims to have discovered that a man had a soul, because he weighed the man while dying, and he weighed one ounce less when dead, and this was because the soul had left the body. This is no proof at all. No doubt dead matter weighs less than live matter. A dead cat probably weighs slightly less than a live cat. Recently an editor claimed a man had a soul was self-evident, because man was the only animal that reasoned. But is he? Do not some

animals reason to some extent? The fact is that there is no proof of the existence of the soul. We have to take it purely on faith.

Speaking of faith reminds us of the story of the priest meeting Pat one day. He said: Pat, do you know what faith is? No, your riverence; will you please tell me?

Faith is believing something that you don't know positively about, but have to take somebody's word for it. You see that steamboat coming down the river? Yes, said Pat.

If I were to tell you there was an elephant on that boat and you believed it, that would be faith. Do you think now you know what faith is? Sure I do, and I won't forget it, said Pat. Well, the next time I see you I will ask you what it is.

Meeting Pat a few weeks afterwards, he said: Pat, what is faith?

Why, it's a steamboat with an elephant on it.

Macroscopical and Microscopical.

How often a physician or student sees in his journal the expressions: *Macroscopical* and *microscopical*, and wonders at the difference in the meaning. To the wise the meaning is evident, but to those who can not fathom the difference we wish to state that there is a wide distinction to be made. *Macroscopical* objects are easily discerned without a magnifying glass—seen with the naked eye. While *microscopical* objects need a microscope to discover them—they are minute lesions. In expert evidence the distinction will be evident and have weight.

The Golden Rule.

We are asked what remedy a good doctor should give his patient. There is only one rule, and that is the Golden Rule: Do unto the patient what you would have the patient do unto you if the conditions were reversed; that is, give the patient that remedy which you have found best, whether the remedy be allopathic, homeopathic, eclectic, proprietary or old woman's remedy, without regard to what the other fellow or the druggist may think about it.

It is only the patient that should be taken into consideration, not any set rule.

Thankful.

The business men of this country are thankful that Congress and most of the Legislatures have adjourned. We do not need any new laws. There is a craze among politicians to regulate somebody or somebody's business. They seem to have forgotten that this is a republic, which it will soon cease to be unless this law-making mania stops.

Timely.

The following editorial from the *Oklahoma Medical News-Journal* is good and timely, and speaks for itself:

We have often wondered why it is, that whether a preparation is in the U. S. Pharmacopœia or not makes so much difference as to its therapeutic value with a certain class of physicians. We see articles on this subject in almost every journal; some denouncing, others defending proprietary preparations. Some claiming or insinuating, it is a crime to humanity, an outrage on science, and a confession of ignorance and inability for a physician to prescribe a remedy whose name is copyrighted.

Now, why this wholesale denunciation? We will all admit there are harmful proprietary preparations on the market, but at the same time, every physician and druggist, if he is at all conscientious, must acknowledge that there are worthless and harmful preparations of U. S. P. drugs on the market. I have a very clear remembrance of an instance of this in the practice of a colleague of mine a year ago. He had given some Bismuth Sub-nitrate (or to use the U. S. P. nomenclature, Bismuth Subnitras) from a package he had just received from a drug firm. Result: Three cases of acute arsenic poisoning. But is that any reason why bismuth, or all the other drugs of the Pharmacopœia should be discarded? No; it only means that the preparations of the firm which manufactured (as the package had come direct from a manufacturing chemical house) that pound of bismuth sub-nitrate were not safe to use. On the other hand, if we get a bottle of H_2O_2 in which there is no H_2O_2 (as we very frequently do unless we specify on the prescription the name of the manufacturers

of the product that we want)—wherefore no result—is that any reason for relegating every preparation of hydrogen dioxide to the dump pile? No; it only shows we should dodge the house which places on sale drugs which have lost their strength.

Why is not this same feeling extended to other preparations not in the U. S. P.? It is usually an easy matter for a physician of ordinary intelligence to tell whether he gets the results he expected from a drug or not; and if he gets these results, why should he not be allowed to use it? Is he not to prescribe a drug, preparation, or formula simply because it is not in the Pharmacopœia (and from some of the articles I have lately read, that is one of the reasons)?

Taking this to be the case: On September 1, 1905, some one hundred drugs were added to the United States Pharmacopœia—likewise some one hundred were dropped from it; one hundred new drugs became official, one hundred which had been official became unofficial.

On August 31, 1905, at 11:59 P. M., I (according to some of those I have mentioned before) would not have been justified in prescribing any one of the one hundred or more preparations added to the Eighth Revised Edition of the U. S. Pharmacopœia. Yet, one minute later, if I had prescribed them under their proper chemical name, I would not necessarily have been classed as an ignoramus. Also the same thing must occur in regard to the drugs omitted from the Pharmacopœia: I must conscientiously say that they are good therapeutic agents before September 1, 1905, but at twelve, midnight, August 31st, I must have my mind so trained that it can conscientiously and honestly say: "They are absolutely worthless, and it is a sin and a crime to use a single one of them."

As I said at first—I wonder why?

It seems to me too much on the order of the "Lady-Bather," whose life had just been saved by a stranger, who, after he had succeeded in getting her safely to land, and she recovered the use of her lungs and tongue, turned to her rescuer and said: "Sir, how dare you—did you not know I had not been introduced to you?"

[Written for the MEDICAL BRIEF.]

Prolapse of the Rectum in Children.

BY GRANVILLE S. HANES, M. D.,
Clinical Professor of Diseases of the Rectum, Kentucky School of Medicine.
Louisville, Ky.

Believing, as I do, that the number of cases of prolapse found in adult life could be materially decreased by proper treatment of such cases in childhood, is the apology I offer for presenting this brief paper. In my own acquaintances I know not less than half a dozen men who have had this condition since childhood, and if proper care and treatment had been practised there is small doubt that all of them would be well to-day in this respect.

This subject is of no little importance when we consider prolapse occurs far more frequently in childhood than at any other time of life—cases neglected and not treated occurring in adult life. Parents alone are not responsible for this neglect in the treatment of children. The physician should take the greatest possible interest in all these cases and show parents how grave such conditions are, and how amenable the average one is to treatment.

Etiology.—The most important etiological factors producing this condition are diarrhea, constipation, phimosis, foreign bodies in the rectum, pertussis, pin worms, polyps, the pernicious habit of allowing the child to remain on the vessel and straining for a long period of time, whooping cough, and anything that will cause undue and prolonged straining. A partial absence of the normal sacral curve is given by many or all authors as a predisposing cause. This I very much doubt. In lieu of this I would suggest that the imperfectly-developed sphincter muscle in childhood is a greater predisposing cause.

Pathology.—There is but little pathology in prolapse in these cases, since it is seldom more than the mucous membrane that appears; the loose, fibrous and elastic tissue upon which the mucous membrane rests, allows a certain amount of protrusion of mucous membrane in expelling the fecal material, and when the act is completed it retracts, and the mu-

cous membrane is replaced in its normal position. If, for any reason, disease or otherwise, these fibers are weakened and lose their elasticity, the protruding mucous membrane is not replaced in the normal way, and, on the contrary, the protrusion grows larger each time the prolapse occurs. In children, the prolapse is usually easily returned. There is not much in the appearance of the mucous membrane, except that there may be a slight redness, and in the cases most difficult to replace, the mass remaining down an unusually long time, the sphincter muscle becomes relaxed, loses its tone, and, in severe cases, becomes paralyzed. Under these conditions the mucous membrane becomes thickened, reddened and ulcerated; as a result of this there may be slight hemorrhages, discharge of pus and mucus, and pain when the bowels act.

Symptoms.—The prolapse is usually from one to two inches in length, and consists of mucous membrane which normally occupies the lowest portion of the rectum. The mucous membrane shows more or less distinct crescentic folds; when the tumor begins to form, the mucous membrane presents the natural color and returns spontaneously; if, however, the prolapse has occurred a great many times and the tumor has gradually grown larger, and is replaced, it then becomes heavy, congested and has a livid appearance. In such cases there are bleeding ulcerations and pain on defecation.

Treatment.—The treatment, I believe, in the main, should be along the lines first suggested by my associate in practice, Dr. J. M. Mathews; however, there are a few points in treatment on which I beg leave to differ with him. Every case must be relieved, after which if the tumor continues to grow, further treatment must be instituted, and, perhaps, the most effective and simple treatment consists in first emptying the bowels with a dose of castor oil, then irrigating with warm or cold water. After peristalsis has ceased, adhesive strips are applied to the nates, holding them closely in position. The child is kept in bed in the recumbent position, and given liquid food. The bowels are allowed to act on the fourth or fifth day by giving an enema or a small dose of oil. If, in the meantime, there is a desire for the bowels to act, a few drops of laudanum may be given, and in such cases the time of confinement should be shortened.

It has been suggested by Dr. Mathews and others that the child lie on its back during the act of defecation, and the perineum well supported by the nurse. I believe that the better position is for the patient to lie on the abdomen; the straining will not be so violent and the nurse can much better protect the parts, thus preventing prolapse during the act of defecation.

After the bowels have acted thoroughly the adhesive strips should be reapplied, and the patient kept confined for three or four days, and the bowels evacuated in the same manner as before. If the case is a severe one, this feature of the treatment may be repeated three or four times. After the patient is out of bed the strips may still be applied, and removed when the bowels act, for several days.

In those cases where the bowel has protruded for several months or longer, the patient should always be in the horizontal posture, either resting on the back or abdomen when the bowels act. This may be kept up for two or three months. It will not, however, be necessary in the majority of cases. When the child is allowed to occupy the natural position at stool, there may be a small amount of cold water thrown into the rectum just prior to the act of defecation. The child should not be allowed to remain on the commode and strain.

If there is a tendency toward constipation, laxatives should be used. A small amount of some astringent may be injected at bedtime. If it should be found difficult to replace the prolapse, a general anesthetic should be given, when the task will be rendered easy.

I believe all ordinary cases of prolapse in children can be permanently cured if the foregoing plan of treatment is faithfully and intelligently carried out; and if such cases were properly treated at this period of life prolapse would be found much more infrequent in adults.

If there should be a rare case where this plan of treatment did not succeed, then some form of surgical intervention would be indicated.

Masonic Temple.

THE MEDICAL BRIEF

J. J. LAWRENCE, A. M., M. D.,
EDITOR AND PROPRIETOR,
NINTH AND OLIVE STREETS,
ST. LOUIS, MO.
NEW YORK OFFICE, ASTOR COURT BLDG.
FOREIGN OFFICE:
AUCKLAND HOUSE, BASINGHALL AVE., LONDON, E.C., ENG.

Syphilitic Diseases of the Nervous System.

BY GEORGE OGILVIE, B. SC., M. B. (EDIN.), M. R. C. P. (LON.).,
Chevalier de la Legion d'Honneur; Senior Physician to the French Hospital, London, and to the Hospital for Epilepsy and Paralysis, London.
London, England.

No. III.

That epilepsy is occasionally produced by syphilis seems to be generally accepted. Of course, I am not speaking of cortical, symptomatic, or Jacksonian epilepsy; its connection with syphilis has long been established beyond doubt; both arterial changes or gummatous growths may lead to it. The knowledge of functional epilepsy as a consequence of syphilitic infection is of more recent date. The question here is of particular difficulty because most of those who accept syphilis as one of the causes of functional epilepsy, yet declare specific treatment to be powerless. Fournier's declarations on this point are also contradictory, as he describes two distinct forms, one which he calls secondary epilepsy, easily influenced by mercury, and a parasyphilitic form upon which the drug has no effect. That in some cases a syphilitic infection is the only possible cause in the patient's previous history, which may be held responsible for the outbreak of his epilepsy, is an argument of doubtful weight, because, in functional diseases in general, and in epilepsy in particular, the most minute search is frequently unable to discover any etiological factor. On the other hand, it is rarely possible to eliminate completely all other causes of epilepsy, such as heredity, trauma, mental shock, alcoholism, acute infectious diseases, heart disease, arteriosclerosis, etc. The neuropathic disposition, in particular, is so indefinite an entity that to exclude it is practically a matter of impossibility. In the etiology of functional disease, and in epilepsy particularly, we have frequently to content ourselves with a Socratean confession of ignorance. It is the "shrewd philosopher" who has a wherefore for every why, not the seeker after truth.

In favor of syphilis as a cause of epilepsy will be its appearance after the twentieth year, or between that time and old age. The first appearance of ordinary epilepsy after forty is not as rare as has been formerly believed, while in the great majority of cases it makes its *début* during the first two decades of life. That every case of epilepsy which is met with after a certain age, say after thirty, is syphilitic is an unwarranted exaggeration. Where there is no history of syphilitic infection, the onset of epilepsy after thirty years of age is still to be observed in from five to seven per cent of the total. My personal experience of syphilis as a cause of epilepsy is small

and inconclusive. It is easy enough to produce cases of syphilitic epileptics, but those with any claim to conclusiveness with regard to the causal connection of the two affections are rare. I do not recollect having seen more than two cases in which I felt justified in attributing the epileptic state to probable syphilitic infection. In one of them a sister of the patient had committed suicide; but the fits, with biting of the tongue and enuresis, appeared first at the age of thirty-three, three years after infection, and led, within six years, to considerable mental decay. It has been stated that syphilitic epilepsy does not, in the course of time, bring on that deterioration of the general mental faculties which, as a rule, follows the genuine form. But here, again, it has to be remembered that there are a good many epileptics who, after long periods of close observation, present no appreciable intellectual defects, while some authors have reported considerable degrees of dementia in cases of syphilitic origin. In my cases specific treatment was apparently of no avail. But to judge of the effect of treatment in epilepsy is a matter of great uncertainty, because there are many cases of epilepsy without a previous history of syphilitic infection, which, without treatment, show long-lasting remissions. That syphilis is among the causes of true epilepsy is a statement which I have to accept on authority, as I am not able to support it from my own observation. The "nature" of this epilepsy, its pathological substratum, is, like that of epilepsy, altogether a matter of mere conjecture. The so-called secondary epilepsy may be due to minute specific alterations in the gray matter of the brain; the parasyphilitic form is by some ascribed to the action of toxins. But little is gained in "explaining" the unproved by the unprovable, *ignotum per ignotius.*

Whether tabes and general paralysis are only two forms of the same process, differing by the localization of the morbid changes, or two distinct pathological conditions, is a question still *subjudice.* It is not my task to describe the clinical or anatomical picture of these diseases, but only to discuss the reasons for which they are generally considered as after-effects of syphilis, and how far this assumption is justified. For this purpose they may conveniently be treated together. It is, therefore, sufficient here to consider the connection between tabes and syphilis. The views expressed in this respect will, with slight modifications, hold good for general paralysis.

A few introductory remarks on the pathological process underlying the clinical picture of tabes are necessary for a full understanding of the question under discussion. Tabes is one of the system-diseases of the spinal cord—a primary degeneration of the posterior columns. But we know, through recent investigations, that the classical picture of tabes, which is familiar to us, may, in rare cases, be produced by a truly specific meningitis compressing the posterior roots, to which the degeneration of the posterior column is only secondary. Syphilis, as I have said before, is intrinsically a mimicking disease. These cases are fitly excluded from the range of true tabes under the name of syphilitic pseudo-tabes. We also know that true tabes may complicate itself with more or less extensive syphilitic inflammation of the blood vessels of the spinal cord. To one or the other of these two classes belong, in all probability, all those cases in which specific treatment is reported to have had a favorable effect. We further know that, as in every other chronic degenerative affection of the spinal cord, chronic alterations of the arterial walls may be found in the cord of the tabetic; but these changes do not represent the primary lesion, and are in no way characteristic of tabes. In an individual case it may, therefore, be difficult to determine with certainty the starting of the morbid process. The view, however, that the degeneration of the posterior columns is always secondary to vascular disease, and that the latter is of syphilitic origin, *i. e.*, that tabes is only one of the examples of spinal syphilis, has been rejected by the most competent workers on the subject. By a general consensus of opinion, in which the adherents of the syphilitic origin of tabes join with its opponents, tabes is regarded as a primary degenerative process in the nerve substance, entirely distinct from genuine spe-

cific disease of the spinal cord. Recently the opinion has been advanced by a neurologist of note that in all cases of tabes the primary lesion is a true syphilitic inflammation of the posterior lymph-vessels of the cord, but up to the present this statement stands without confirmation. Consequently we must accept the primary non-specific nature of the tabetic process as an established fact.

"Syphilitic, not in nature, but in origin"—this was the definition given of a parasyphilitic lesion. Now let us consider the facts upon which the syphilitic origin of this non-syphilitic disease is assumed. The most important arguments for it are certain statistics, which prove the existence of previous syphilitic infection in patients suffering from tabes; but before submitting these statistics to a closer analysis I shall briefly mention the other facts pointing in the same direction. It has long been observed that both tabes and syphilis of the central nervous system affect, with predilection, certain nerves or groups of nerves, in particular those supplying the ocular muscles. These ocular palsies are frequently transitory in character; in both the optic nerve is prone to be affected, and the pupillary and patellar reflexes are influenced in the same manner. A number of cases have been reported in which syphilis acquired late in life was followed by an uncommonly late appearance of tabes. Tabes has been found in both husband and wife; in such cases there is always a clear history of syphilis. In other instances one of the two suffers from tabes, the other from general paralysis. Here, too, previous infection can be proved in at least one of the patients. Inoculation experiments with fresh syphilitic virus on persons suffering from general paralysis have given negative results; similar experiments on the tabetic are not known. Although in most cases of true tabes there is no corroborative evidence arising from syphilitic affections of other organs, there exists now a series of cases in which such co-existence has been observed. In particular, in cases of infantile tabes and general paralysis there is frequently certain evidence of congenital syphilis. In the absence of *post-mortem* examination, however, it must remain doubtful whether these cases do not belong to the category of pseudo-tabes. At a comparatively early age tabes has been observed, together with aneurysm of the aorta, apparently due to arterio-sclerotic changes. Childlessness is frequent in married women suffering from tabes, and may be due to want of conception, to abortion, or to the early death of the child—usually occurring during the first month. I cannot here discuss at full length the relationship between each of these facts and the question under consideration. If taken singly, some of them may be open to a different construction; yet, taken together in their entirety, they undoubtedly strongly support the causal connection between tabes and syphilis. The most important argument in favor of such connection is, as I have said, derived from certain statistical inquiries. Here, however, the results vary between the widest limits. While some have found not more than from fifteen to twenty per cent of syphilitics among the tabetic, others report ninety per cent, and more. It is impossible to estimate accurately the spread of syphilis among a population. But from certain statistics collected in hospitals and private practice, it seems that in patients suffering from other nervous diseases than tabes or general paralysis, or from other diseases, whether nervous or not, a history of syphilis may be traced in about twenty per cent. Perhaps Fournier's estimate for Paris, that between fifteen and twenty per cent of the population are syphilitic, comes near the truth also with regard to other large cities. If these calculations are only approximately correct, it will appear that, according to some observers, the percentage of syphilis in tabes is not greater than what corresponds to the general distribution of that disease; while others report exorbitant figures, even approaching one hundred per cent. According to the former, syphilis would have no part in the production of tabes; according to the latter, it would be its predominant, if not its only cause. Moebius, for instance, and Marie consider syphilis as the exclusive cause of tabes. According to them, every case, without exception, is of syphilitic origin. Indeed, if the ninety-and-more-per-cent statistics

were reliable, this seems to me the only possible and unavoidable conclusion, for the simple reason—as far as I know, not yet pointed out—that these numbers are far in excess of those which are obtainable in cases of undoubted tertiary syphilis. For this very reason I believe that these excessive statements are not trustworthy. Neisser, the discoverer of the gonococcus, has for many years carefully collected the evidence of previous infection in cases of undoubted tertiary syphilis, in order to study the effect of specific treatment in the prevention of tertiaries. Only such cases were entered in his statistics in which the diagnosis of tertiary syphilis was "absolutely certain," and in which there were reliable dates regarding previous treatment. He consequently excluded cerebral and visceral cases of doubtful origin—parasyphilitic affections like tabes, general paralysis, leukoplakia, also malignant syphilis. Yet the percentage of cases in which the infection was "unknown," in which the tertiary lesion was the *first appreciable manifestation* of the disease, varied from between thirty and fifty per cent. Fournier, among his cases of gumma of the tongue, found more than forty per cent without evidence of previous infection. Similar experiences have been reported by other observers. These numbers seem to me to be in flat contradiction to those reported in cases of tabes, unless tabes is a disease *plus syphilitique que la syphilis*. A close consideration of some of these extraordinary statistics seems to confirm the opinion thus formed of their validity.

Some years ago Fournier gave a summary of a thousand cases of tabes. The cases were "chosen from among many others." He made it a point to include only "precise, incontestable facts, relying on information intelligently given by the patient, on well-established antecedents, sometimes even on actual manifestations of syphilis. In one word, a thousand cases where either the existence or the absence of syphilis in the patient can be affirmed categorically." This eclectic character of his series seems to deprive it of most, if not of all, demonstrative power. In the first place, to exclude, categorically, syphilis is an utter impossibility, particularly if one believes like Fournier, that congenital syphilis may, with or without previous symptoms, make its appearance up to the age of sixty. But in order to determine the percentage of syphilitic infection it is indispensable to include all cases of tabes. The large number of cases, the "many others" in which previous infection remains doubtful or could not be proven, although it could not be "excluded," form as important a part of the statistical material as those either strictly negative or positive. This omission is the fundamental fault of Fournier's calculation. Once more syphilographers' statistics are bound to be at variance with, and less conclusive than, those of the neurologist, because only those with a history or a suspicion of syphilis will, as a rule, seek his advice, while the others will remain with the neurologist, or general physician. The result of Fournier's eclecticism is that he finds ninety-two or ninety-three per cent of certain syphilis to seven or eight per cent without antecedents, and he adds that this "quotient is a minimum only," because, in from six to ten per cent, syphilitic antecedents are missing in any syphilitic affection whatsover. The contradiction in which he thus entangles himself is obvious, and is further increased by the emphatic statement that syphilis is *not the only cause of tabes*. If these eight per cent (the average between six and ten) have to be added in every syphilitic affection whatsoever, then we have for tabes a hundred brimful, and there is no other cause of tabes possible but syphilis; but then it also follows that in his eight per cent without syphilitic antecedents, the absence of syphilis could not be "categorically affirmed." Although I am not a "great arithmetician," like Cassio, yet I make bold to maintain that these more-than-ninety-per-cent statistics are fictitious and fantastical figures.

I want briefly to refer to another statistical inquiry relating to the same point which also seem to me open to some criticism. Byron Bramwell published in *Brain* an interesting and instructive analysis of one hundred and fifty-five cases of tabes. On the point in question, viz.: The connection between syphilis and tabes, I cannot approve of the course

adopted by him. He does not attempt to discriminate between hard and soft sores, and, consequently, takes a venereal sore with or without secondary symptoms as evidence of syphilis. This must materially impair the validity of his conclusions. Not only the soft sore, but, for instance, herpes of the prepuce, may also be included in his statistics. He suggests that the toxins of the *soft* sore may produce the same effect on the nervous system, but up to the present we know nothing of the constitutional effects of the *soft* sore, much less of its toxins. In all probability the *soft* sore is not a pathological unity, but may be produced by several micro-organisms. Dualism, which, thirty years ago Hutchinson pronounced to be "dead if not yet buried," seems to have revived and regained its old position.

If, for the reasons given, the excessive percentages arrived at by some observers are open to doubt, there yet remain other statistics which seem more worthy of credence, and would testify in favor of a close causal connection between tabes and syphilis. Gowers, for instance, found fifty per cent, and others have come to similar results. Even these numbers would, in the light of what I have said above regarding the evidence of past syphilis in tertiaries, go far to establish syphilis as a potent, if not the only factor in the production of tabes. Indeed, taking this numerical evidence in connection with the other arguments briefly referred to, there seems to be a little doubt about the syphilitic origin of tabes, a conviction impressed upon me by personal experience. Yet there remain certain apparently well-authenticated facts which seem to be in opposition to this doctrine. Among them, the most important seems to be that in districts and among tribes where syphilis has for long been raging endemically, *tabes and general paralysis are practically unknown.* The observations made by Neftel, Irennen, Jeanselme, Düring, Glück, and others in different parts of the world, agree that a population, although thoroughly impregnated with the syphilitic poison, may yet present *no specimens* of these "parasyphilitic" affections. Of general paralysis it has been said that for its development the co-operation of "syphilization and civilization" is necessary. This *bon mot* would hardly apply to tabes, because the seat of civilization is not situated in the posterior columns of the cord. The rarity, also, with which prostitutes present tabetic degeneration is difficult to reconcile with its syphilitic origin. Yet, on the whole, it must be said that the evidence in favor of a close causal connection between tabes and syphilis is exceedingly strong, although some facts remain which seem to point in the opposite direction.

[Written for the MEDICAL BRIEF.]

Food and Feeding in the Tropics.

BY D. J. JONES, M. B., C. M. (EDIN.),

Deputy-Coroner, South Breconshire; Late Chief Medical Officer Government Railway, Lagos, West Africa, and to the Government Railway, Bristol, North Borneo; Late Medical Officer, Government Surveys, Ashanti, West Africa, London, England.

Considerable attention has been paid of late to the subject of dietetics; in other words, to the regulator of food and the principles and practice of feeding. It is of vital importance, not only to the individual but to the prosperity of nations. It involves many important considerations, and its discussion demands not only a knowledge of the digestive processes carried on in different portions of the alimentary canal, but an intimate acquaintance with the general principles of metabolism.

Having spent many years of my life in the tropics, I am naturally interested in all that appertains to the hygiene of hot climates, and especially to the regulation of diet, both in health and disease. It is a subject on which much has been written, and it is generally admitted that the climate of a country exerts a marked effect on the health and character of the inhabitants. The power of endurance of Europeans settled in India is often severely taxed, though the strain is often due more to the habits of the individual than to his environment. There is no question that by the exercise of reasonable precautions immunity may be increased, and that with care anyone not suffering from organic disease may adapt

himself to the altered conditions of existence, and to extremes of temperature and climatic change. It is especially in India that the subject is of paramount importance, for, without attention to these matters, health is impossible. Sir Joseph Fayrer (*Preservation of Life in India*, 1894) points out that "Exposure to the direct solar heat or to a high temperature in the shade may induce heat exhaustion, ardent fever, heat asphyxia, and other evils of a more insidious character by injuring the nervous system, increasing irritability, depressing vital energy and affecting the internal organs, especially the liver, which is already overtaxed by eliminating waste products, and compensating for the diminished respiratory excretion of carbonic acid through the lungs, the consequence of breathing a more rarefied and, therefore, less oxygenated atmosphere. In hot climates the blood becomes deteriorated; there is a tendency to liver affections, fever, boils, and a variety of ailments."

The chief points to which attention must be directed are the observance of simple hygienic rules, the avoidance of exposure to excessive heat, and other obvious causes of disease, and, above all, strict observance of dietetic considerations.

That the mortality amonst children born in India is high is a matter of common knowledge. The injudicious feeding of a child in the first twelve months of its existence, either destroys its life or leaves indelible traces on its physical conformation. The ill-nourished child must be sent to Europe, or it will deterioriate slowly but surely. The physical change is not easy of definition, and is not readily described, but there is a general progressive feebleness, and want of tone, readily recognized by the trained observer. In adults, excepting those of the most robust constitution, the effects are characteristic, and the influence of a tropical residence on Europeans is sufficiently indicated by the waste of health which ensues. The nervous activity is at first, and for a short period, improved, but it soon undergoes a process of deterioration. To preserve health under such difficult and exceptional circumstances attention must be paid to clothing, to the selection of a habitation, to the question of judicious exercise, and, above all, to the regulation of the diet.

It is generally admitted that a regiment which is well adapted to a cold climate, is ill-suited to the requirements of those living in a much higher average temperature. The consumption of meat and of richly flavored dishes so common in England, are entirely out of place in India. Sir Joseph Fayrer says:

"With regard to diet, it should be plain and simple; for new arrivals it is better to abstain from much animal or stimulating food, with the view of avoiding plethora, dyspepsia, malassimilation and congestion of the liver. Moderation is necessary, but it is not expedient to imitate too closely the natives of the country in the character of their food. The stomach of the European will no more obtain from the diet of a Hindoo all that is necessary for nutrition than it could in other circumstances from the blubber that delights whilst it nourishes an Esquimo. Habit, in these things, becomes hereditary, and our machinery is not adapted for sudden changes. But the principle of simplicity is sound, and the food should be modified to suit changed circumstances. As a general rule people eat too much in India—more than they can assimilate, or is needed for nutrition. The consequence is derangements of digestion, faulty assimilation, disordered liver and engorged portal system; bowel complaints, and the presence of effete matter in excess in the blood."

It must be admitted that with many people animal foods constitute the most attractive and appetizing form of diet, so that there is great danger of this being taken in excess; that is, in quantities beyond the oxidative powers of the tissues. The necessity for limiting the amount ingested under circumstances not favorable for its combustion is apparent.

The classification of foods necessary to support life in its highest state of vigor is based on the fact that milk, the staple food of the infant, contains all the alimentary substances necessary for life and growth, and the nearer the dietary approaches that simple standard the more likely is it to be assimilated and to supply those essential materials without

which the production of energy can not be efficiently maintained.

Pure milk, however, is not so easily procured as might at first sight be imagined. In England it is usually drawn from the cow, but in India milk from the goat is also used. Goat's milk is richer in cream, but poorer in proteid matter than the milk of the cow. There are objections to its use, for goats are dirty feeders, and in India are allowed to roam anywhere in search of food. It must be admitted that the same objection applies to a very great extent to cow's milk: Dr. Andrew Davidson (*Hygiene and Diseases of Warm Climates*, 1893), says:

"In India and in the tropics generally cows are often fed on the litter from stables, and the places in which the animals are kept are filthy; their limited supply of food leads them to feed on any sort of garbage. It is wise, therefore, to use no milk which has not been previously boiled; if it is possible to do so, the feeding of the animals and the milking should be under supervision, but the use of raw milk should never be permitted. Milk which has been boiled should be so guarded from contamination by keeping it in a perfectly clean and well-ventilated place, that there can be no danger of its becoming infected by dust or flies. In India, where cholera is endemic, special attention should be paid to this point, as it has been shown that the danger is greater when boiled milk is used, as boiling delays the acid fermentation of the milk, which, of itself, helps to inhibit the growth of the cholera organism."

In my own practice I endeavor, as far as possible, to obtain a supply of milk from farms, the water supply of which is above suspicion, for contaminated water is one of the most fruitful causes of milk infection. What I require and insist on having; is a pure, clean milk of a specified quality, derived from healthy cows, not under physic. In addition, it must be properly strained and cooled, and protected against contamination and infection. This, in England, at all events, in all large towns, presents no difficulty, but in India and tropical countries generally it is impossible, so, that as an article of diet, especially in illness, milk has to be employed with caution and reservation.

An excess of proteids, especially in the form of meat, causes rapid metabolism and tissue change, which, if not counteracted by an amount of active exercise impossible in hot climates, results in the overloading of the blood with unoxidized products, and with the appearance in the urine of urea, uric acid and possibly albumin.

Foods for all practical purposes may be divided into two classes. (1) Organic, and (2) Inorganic. The inorganic substances are water and mineral substances, such as the salts of potassium, sodium and lime, together with minute quantities of phosphorus and chlorine. Some of these ingredients are held in solution in the different beverages which we drink at meals, or between meals, and others are supplied in common table salt.

The organic nutrients may be divided into those which are nitrogenous and those which are non-nitrogenous. Amongst the nitrogenous foods we include proteids, of which the most familiar examples are casein, myosin, gluten and legumin. The non-nitrogenous group includes the carbohydrates, of which sugar and starch are common types, and fats, such as butter.

Different classes of foods fulfill different functions, and it is especially to the proteids and the inorganic materials we look for building up and repairing the tissues, and generally keeping the human machine in order. For many years it was believed that the carbohydrates and the fats were used solely for maintaining the temperature of the body, but this is erroneous, and we now know that all forms of food may be utilized for increasing strength and activity. In spite of this proviso, physiologists are agreed that the proteids are the most potent factor in tissue formation, and in keeping body and mind in their highest state of efficacy. In temperate climates meat forms the staple article of diet, whilst in colder climates there is usually a plentiful addition of fat. In the tropics, where the mean diurnal temperature is high, it is found as the result of experience that it is impossible to eat much meat, and that when the consumption of it is large it is not assimilated, and gives rise to gastro-intestinal disturbance, eventuating in chronic diar-

rhea and dysentery. Meat extracts have practically no nutritive value, so that it is necessary to seek for some form of proteid other than meat. Gelatin is not a substance suitable for the purpose, for it is not capable of tissue formation, and is in no sense a substitute. A man fed solely on jelly would soon die. In casein, the principal proteid of milk, we have a perfect substitute both for crude milk and for meat. It contains no nuclein, and yields no uric acid, so that it is especially indicated as a dietary for gouty people. Moreover, it yields no carbohydrate when split up, and may be used with perfect safety in cases of diabetes. It is a tasteless, compact, easily digested proteid. Resorption is so complete that there is no possibility of its undergoing fermentation in the intestines, even should it not act, as some have supposed, as an intestinal antiseptic. It is digested with ease, and is absorbed in its entirety—a point of some importance, for the value of food depends, not only on the percentage of nutritive material it contains, but also on the readiness with which it is assimilated. Another valuable peculiarity and property of casein is that it contains phosphorus, an important constituent of all tissues. Dr. C. D. F. Phillips, both in his *Materia Medica and Therapeutics* and in his recent articles in the MEDICAL BRIEF (November and December, 1906,) has dwelt so fully on the therapeutical properties of phosphorus that it is not necessary that I should dilate on that point. It must be remembered, however, that the quantity of phosphorus contained in casein itself is small, and that any preparation of casein containing a larger percentage of phosphorus is an organic, and, consequently, readily assimilable, for it has the greater advantages, both as a food and as a stimulant to the growth of tissue. The whole question of lecithin derivates is a complex one, but is well worthy of study from the point of view of applied dietetics. I have dealt more fully with this aspect of the subject in my paper on "Food and Feeding in Alcoholism" (MEDICAL BRIEF, *and Circular*, 1905).

Reverting to the treatment of diseases incidental to tropical life, we find that disorders of the stomach, intestines and digestive organs generally are more frequent than in Europe. With regard to the symptomatology and the pathological changes met with in these complaints, they exhibit no material differences from those of the temperate zone, with the exception that they more frequently assume a chronic character, causing emaciation, anemia, and frequently death. Their frequency is explained by the sensitiveness of the intestinal canal peculiar to the tropics, and attributable to the altered conditions of the circulation, and the atony of the intestinal muscles, rendering the mucous membrane of the intestine more easily affected by infectuous lesions than they would be under normal conditions. Errors in diet, contributed to by the rapid decomposition of articles of food, and by the tendency to chills, furnish incidental causes.

Speaking of tropical dysentery, Scheube (*Diseases of Warm Countries*) says: "Dietetic treatment is of greatest importance, and should always go hand in hand with other remedies. In acute dysentery only fluid food must be taken until an improvement occurs. Boiled milk, taken lukewarm, is the best, and if the patient can not take it pure, the addition of a little soda water, lime-water (a tablespoonful to the cup), or even a little tea, coffee or cocoa is permissible. Where fresh milk is unattainable, unsweetened condensed milk can be given. Next to milk, gruels and farinaceous foods are recommended, also thin soup, beef tea and meat juice. In chronic dysentery a pure milk cure is most suitable first of all, later on its place may be taken by a digestible but strengthening diet."

It will be noted that much reliance is placed on a pure milk diet. With this I am in accord, but undoubtedly many chronic dysenterics are unable to assimilate the large quantity of milk—three pints or more—necessary to furnish them with the requisite amount of nourishment to enable them to maintain body-weight. In these cases the addition of a certain proportion of casein to the milk will be found advantageous. This accords with the principles laid down by Sir Patrick Mansor (*Tropical Diseases*, 1900), who says:

"Were it possible, it would be well to stop all food; this, of course, is impossi-

ble, so we make a compromise between the therapeutical indication and the physiological necessity by reducing the diet to a minimum, and selecting only such foods as, while possessing considerable nutritive value, yield but a small fecal residue."

With regard to Mediterranean fever, Malta fever and their prototypes, it must be remembered that formerly they were treated with a variety of depressing drugs, such as antimony, with the result that the patient rapidly became anemic. A more recent custom was to give phenacetin, salicylate of sodium, and other anti-pyretics in large doses, with the effect of weakening the heart's action, and rendering the patient less able to resist the ravages of the disease. Fortunately, rational therapeutical measures are now in vogue, and we rely to a very great extent on the judicious administration of nervine stimulants. The patient is no longer kept on a pure milk diet, and the stomach and intestines are not distended with indigestible foods, and the products of their decomposition. Strength is maintained, and the patient is encouraged to make a good fight for life by giving him food which he can digest, and which serves to stimulate the nerve cells of the brain and cord.

In sprue, which is prevalent in India, China and Java, and of the causation of which little is definitely known, drugs alone are of very little use, and the treatment consists of absolute rest in bed with a dietary consisting chiefly of casein and the glycero-phospates. This is better by far than milk alone, for lecithin, even in minute dose, exerts an extraordinarily favorable influence upon nutrition, its effects in this regard being catalytic, or of the nature of a ferment. In the treatment of this disease, and as a means of combating its depressing influence, reliance may be placed on this regimen combined with physiological rest. As accessory measures I have no objection to the occasional administration of a raw egg, or of a little boiled arrowroot, but meat extracts and meat juices do more harm than good.

The same mode of treatment is applicable to beri-beri, a curious form of multiple neuritis of unknown etiology, prevalent in the Malay Archipelago, in China, Japan, the West Indies and some parts of Burma. It is especially apt to prove fatal when the neuritis affects the vagus nerve, giving rise to irregularity of the heart's action and breathlessness. There is no more remarkable triumph of modern hygiene than that which followed dietetic reforms at the instigation of the Japanese physicians. A remarkable diminution in the disease followed the continued use of a diet rich in nitrogenous ingredients.

The same general principles of treatment apply to malarial fevers, Malta fever, and most other diseases incidental to hot climates.

I have endeavored in this paper to emphasize the fact that the laws of nature conduce to the adaptation of the supply of food to the demands. We all recognize the fact that cold or exercise sharpen the appetite and increase the desire for food. A warm, enervating climate has the opposite effect, and dulls the appetite. It is better to realize this fact, and in tropical climates to make milk and fruit, with a small allowance of meat the staple articles of diet. When milk, in a condition of purity, is unobtainable, we must rely on what may not inappropriately be called the active principle—casein. What is applicable to a condition of health under these circumstances holds with the more force in all attacks of others attended with elevation of temperature, whether bacterial in origin or not.

[Written for the MEDICAL BRIEF.]

Squint and Ocular Paralysis.

BY E. LUCAS HUGHES, L. R. C. P. (LOND.), M. R. C. S. (ENG.),

Fellow of the Royal Institute of Public Health; Late Ophthalmic Surgeon to the Hope Street Hospital.
Liverpool, England.

II.

Binocular, single vision, finds its highest development in man, and it is upon this fact that the whole subject of extrinsic ocular muscle anomalies seems to hinge, for animals, having only a much less degree of binocular vision, are never noticed to squint, except in the rare cases

of the paralytic variety, due to some lesion of orbit, optic nerve tract, etc. Paralytic squint is almost always associated with, as its most prominent symptom, binocular double vision or diplopia. In cases of ocular paralysis the squinting eye is not the eye that is really affected, *i. e.*, it is not the eye with the paralysis, but it is the other one. This is due to the fact that neither squint—an objective symptom of ocular paralysis—nor diplopia, the subjective symptom, come into play at all, except when there is a binocular associated movement towards that side where there is the paralyzed muscle or muscles. Take, for instance, the two muscles which have associated binocular movements to the right or to the left; the left internal rectus muscle pairing with the right external rectus, and right internal pairing with left external. Say one of the externals is paralyzed, the right external; what happens? Does the right eye show any squint? No; it can not move to the right beyond a certain point; as soon as it reaches the area normally controlled by the right nervus abducens with its muscle it stops, it can go no further; the healthy partner in this binocular movement is able to turn the left eye, however, to the very fullest extent, which, indeed, it does, causing an extreme degree of convergent squint. The innervation, which fails in the one eye to bring about the desired movement, is altogether too much for the healthy eye, and it is consequently this eye that squints, or, in other words, overacts its part, when called upon to look to the right; the side where there is the paralysis in its fellow. When the eyes look away from the paralyzed side there is no squint and no diplopia, but diplopia and squint both become manifest when an attempt is made to look in the direction of the affected muscle. Theoretically, there should be some amount of strabismus of the paralyzed eye, but, as a matter of fact, equilibrium is maintained fairly well on account of the accessory abductors being unaffected, *i. e.*, the two oblique muscles.

Similarly, the accessory abductors could maintain balance, if there were paralysis of an internal rectus. A paralyzed eye can, therefore, fix so long as it is looking at a point outside the area of its paralysis, but, owing to nerve force, meeting a check in the one, and becoming excessive in the other, neither eye can be said to properly fix in ocular paralysis when looking at a point inside the visual area of the paralysis.

Ordinary functional squint is thus seen to be an entirely different affection from the squint which is associated with ocular paralysis (strabismus paralyticus, or luscitus). The functional variety is present in all directions in which the eyes are turned, and the squint is always to the same extent. In the functional case the one eye squints while the other fixes; in the paralytic the one eye squints while the individual is struggling to do what the paralysis has rendered impossible, *i. e.*, to turn the paralyzed eye to the affected side. The more the effort is made the more becomes the squint in the paralytic variety, but in the functional variety, the two eyes are, relatively to each other, at a wrong angle, which does not vary.

Functional strabismus, or concomitant squint, is essentially a condition of childhood. Ocular paralysis may occur at any age. The latter is a pathological manifestation of some disease, brain lesion or some other more or less serious condition, whilst the former is the result of some educative defect, associated with the development of binocular single vision. Concomitant strabismus is nearly always either convergent or divergent, and, as is well known, closely associated with errors of refraction, usually, but not always, with hyperopia in convergent cases and myopia in divergent; paralytic squint may be in any direction, according to the muscle that is paralyzed, the overaction in excessive innervation, or the unopposed action of a muscle, as may sometimes be the case, although rarely so entirely unopposed as to cause a constant squinting of a paralyzed eye.

Two fundamental errors have, in the past, falsified our ideas on the nature of functional (non-paralytic) strabismus. One has been that of attributing the deviation of the eyes simply to a supposed muscle defect, and the other has been the identifying of squint with this deviation. Unlike strabismus, of course, the squint

of ocular paralysis is really owing to a muscle defect, *i. e.*, the paralysis, the opposite muscle being able to act unopposed, or, as explained above, an overacting muscle causing a very pronounced squint in the other eye, that muscle being associated with the paralyzed muscle in binocular movements. But, even here, squint is only a symptom; even the paralysis is not all that we have of the disease; there is the lesion at the floor of the fourth ventricle, or elsewhere, whether it is paralytic or functional. The actual squint is, therefore, seen to be only a symptom, in the past mistaken for the whole disease. Pott's disease might just as well be dedeseribed as "a deviation from its normal shape." We should be extremely sparing of operations when the squint is the result of ocular paralysis. At the onset these cases call for medical treatment. The deviation is often transitory, and generally caused by a nuclear lesion due to tabes, syphilis, intoxications, etc. Only after prolonged medicinal treatment, and when the paralysis has become well established and well defined, the patient suffering great discomfort from diplopia, should operation be thought of.

Convergent functional strabismus needs to be considered separately from the di vergent variety, as its etiology is quite different. It is best defined as a lack of development of the faculty of fusion, so that proper binocular vision is unable to take place, this resulting in the deviation inwards of the visual axis of one of the eyes from its correct position of fixation. There are, therefore, two essential conditions in every case of comitant convergent squint. One is a defect of the fusion faculty and the other is an abnormal convergence of the visual axis. Other conditions arising from these two fundamental ones, or at least associated with them, are (*a*) the presence of some error of refraction, nearly always hyperopia or hyperopic astigmatism, (*b*) suppression of the vision of the eye that squints, which quickly results in a functional but only central (macular) blindness, termed amblyopia exanopsia, or loss of central vision of an eye from disease. (*c*) In rather rare cases this emblyopia is not an acquired one; it may be pronounced congenital, if there be sufficient evidence in the history of the case to take that view.

A child is so young and suppression of the vision of one eye takes place so soon, almost *pari passu* with the development of the deviation that no diplopia is experienced by the patient. Here it markedly differs from the squint of ocular paralysis, where diplopia is the most marked and constant subjective symptom, in most cases, indeed, the one symptom that troubles the patient.

The amount of squint should always be measured. This is most readily done by comparing the two small reflections of a light or mirror, in the dark room, thrown quickly onto the two corneas (Hirschberg's mirror test); more accurately by the Maddox tangent scale, by the perimeter, or by Worth's deviometer. The visual acuity should always be taken of both eyes, but especially of the squinting one. This is done by means of balls of different sizes thrown across the room, these being made for the purpose, as much as possible to correspond with Snellen's or Wallace's type scales. I have recently devised a type card of brightly colored animals, in nine different colors, the smallest line of animals being about the size of D-6 (Snellen's letters). These are in very pronounced colors. The child is asked to look at them and say what they are; a blind hiding the upper ones, which can be gradually pulled up if the child is unsuccessful in the lower. It saves the child running about the room and knocking against things. The child is immensely taken with the pictures, as they are gradually uncovered, and exclaims: "Geegee," "baa lamb," "doggie," etc., as he sees them revealed. To find the separate movements of the eye a silver ball suspended by an elastic cord can be dangled in different directions before the uncovered eye; first one eye being covered and then the other. This is much better than the surgeon's fingers, being an uninteresting object to the child. A point to be early determined in every case is the amount of dynamic convergence. This is estimated by bringing the object looked at, the surgeon being at arm's length, and two eyes being uncovered, closer and closer to the fixing eye.

It is obvious that orthoptic measures can only be successful in concomitant, *i. e.*, functional strabismus. I have been very successful in all cases where the squint has not exceeded twenty degrees of convergence, and the amblyopic condition of the squinting eye has not been too long established. My method is to ring the changes with Worth's amblyoscope and the ordinary steroscope of Holmes. With the amblyoscope I make use of the brightest and strongest electric transmitted light I can get, so as to compel both eyes to see the two objects simultaneously. If there be any suppression of vision in one eye, I give atropine for the fixing eye only, and only for a week or a fortnight, at most, so as to develop the vision of the squinting eye. Then I try again with the amblyoscope until the child can see and bring together the two pictures. Half the battle is then over. I can pronounce then a hopeful prognosis, providing the exercises are patiently continued, the tendency to amblyopia having been conquered. Convergent squint which is not due to lack of development of the fusion faculty, the common cause, is always due to a breakdown of the balance of muscle power in adduction and abduction of the eyes. The tendency to this breakdown is termed muscular insufficiency or heterophoria, and the term heterotropia is given by British oculists for the manifest squint that ensues owing to this breakdown. Cases of heterotropia, the term used in this limited sense, are very rare. If seen soon after the occurrence of the squint, they can be cured with a little patient endeavor, by means of the ordinary stereoscope, bimanual drawing, etc. If allowed to continue for long, of course, they call for operation.

The ordinary squint of children, due to lack of fusion faculty development, is an internal strabismus, and nearly always develops before the age of seven, usually at the age of three years. The earlier the squint develops the more rapid will be the suppression of vision, going on to amblyopia, of the squinting eye, so that with well-marked amblyopia at seven years of age, the squint having been manifest for some time, the hope of a cure by non-operative treatment is not great. The younger the child and the less the duration of the squint the more hopeful the prognosis. The rare cases due to loss of muscle balance (heterophoria) occur in much older subjects, nearly always young adults, or adolescents, never in children. I have, however, recently had a case where the age has been as young as thirteen years for the onset of the actual squint. Older children, like those of this age, who are myopic, commonly develop a divergent squint, but these have nothing whatever to do with the heterophoria cases (heterotropia). Divergent squint resulting from myopia will be dealt with in a subsequent paper. A case of heterotropia seen recently is as follows: W. C. G., aged fourteen; schoolboy. Father died of consumption at the age of forty. Mother alive; healthy; aged thirty-five—no ocular trouble. When he came home for the holidays last Christmas, mother noticed for the first time, a "stand," "as if the eyeball turned in." No squint had ever been noticed before then. She took him to an oculist, who ordered him glasses, +0.5 spherical, for reading. He never complained of any pain or headache. The squint seemed to have been only occasional at first, but lately it has been much more constant. On inspection of the eyes nothing abnormal can be made out, except a distinct squint of the right eye, about 15°. Vision of R. eye $\frac{6}{6}$, H. M. O. 5^{6}_{6}, L. eye $\frac{6}{6}$, H. M. O. 62^{6}_{6}. The mobility of the eyes is good in all directions. Well-marked esophoria is discovered by Maddox rod test, etc., requiring a 12 $\triangle$ prism, apex in, to overcome. As the boy was going back to school the next day it was not advisable to work out his refraction with a cycloplegic, but he obviously had a slight degree of simple hyperopia, and he was ordered to continue what he was wearing for reading only. It was also advised that he should have stereoscopic exercises, while at school, using Holmes' stereoscope and Kroll's pictures for half an hour every day, with bimanual drawing, two or three times a week. January 2, 1907.—Patient has been having the exercise as directed, and the eyes are very much better. The mother was in fear and trembling when she went to meet him at the railway depot, and was agreeably surprised at the marked change in his appearance. There still remains about

3° to 5° of internal strabismus; R. eye measured by Maddox tangent scale. He can blend in the stereoscope up to I. 9 of the Emil Hegg series. Can manage all the Kroll cards except one. January 14th.—The boy has been coming every morning, the last ten days, for an hour's exercise. He soon succeeded with all of Emil Hegg's cards, and then with Javal's cards. Can spell out all the French words of the latter. I have, therefore, given him several cards of my own design, making them as difficult as possible.

He can blend ordinary handwriting in duplicate on a card, as well as the very fine print; reading it all without difficulty, even when thick lines are drawn across many of the letters: V. $\frac{6}{6}$ with both eyes. There is now orthophoria for far and near. His squint has completely disappeared, and his mother is delighted with the cure.

The diagnosis in this case rested upon four factors, namely: (1) The only slight and almost equal amount of refractive error, (2) the age of onset of the squint, (3) the absence of amblyopia (+0.5 spherical giving him perfect vision), and, (4) the well-marked esophoria, at once discovered when his muscle balance was examined with the Maddox rod.

Diagnosis and Treatment of Measles.

BY H. M. MCCLANAHAN, A. M., M. D.,

Professor of Pediatrics in the College of Medicine of the University of Nebraska.
Omaha, Neb.

There is in measles an inflammation of the mucous membrane involving the eyes, nose, throat and trachea. This is undoubtedly due to the poison throwing out an eruption upon its surface, following this is the eruption upon the skin, the macular spots, and when this has appeared the eruption upon the mucous membrane should subside.

The recognition of Koplik's spots is the most important diagnostic symptom, and by means of this symptom diagnosis can be made from two to four days before the appearance of the eruption. In a child with a temperature of 102°-3°, decided bronchial cough, suffused eyes, etc., Koplik's spots should be searched for. It is necessary to have the child in a good light in order to discover these spots, and the entire buccal cavity should be carefully inspected. In my experience they usually appear on the inner side of the lips and cheeks; they are small, pearly-white spots, slightly raised, and when seen in a strong light, are quite distinct. They are readily overlooked, because it is only recently—or within the past few years—that they have been recognized as a diagnostic symptom of measles.

During the prodromal period the temperature is out of proportion to the local signs and symptoms. It is not unusual to have a temperature of 102°-4°, with a severe cough, and yet no râles in the lungs to indicate any inflammation of the air vesicles.

There is little difficulty in diagnosing measles or in differentiating the disease from Rötheln or German measles, if the following differences are kept in mind:

1. The slight prodromal stage in the German measles in contrast with the marked symptoms in measles.
2. The enlargement of the post cervical glands which is constant in German measles, these glands being both enlarged and tender.
3. The absence of the Koplik's spots.
4. The rash in German measles is lighter, the maculæ are smaller, and the eruption disperses itself over the body more quickly.
5. An attack of measles does not protect against German measles, and *vice versa*.

When diagnosis has been made, the child should be put to bed, and kept there until the eruption has faded. In this way it is possible, in my judgment, to prevent the occurrence of broncho-pneumonia, which is such a dangerous complication, and adds so greatly to the mortality of measles.

Another and very serious complication of measles is catarrhal laryngitis, producing severe dyspnea. There are cases of this type which it is almost impossible to differentiate from laryngeal diphtheria, and, indeed, in doubtful cases, diagnosis can only be made by the culture test. That is, swabbing the throat and determining

the presence or absence of the Klebs-Loeffler bacillus.

Otitis media is another complication of measles not sufficiently recognized. My observations lead me to believe that this complication is as frequent in measles as in scarlet fever, although the inflammatory action is not so destructive to the structures of the middle ear as in the latter disease.

The physician should also be on his guard for nephritis. This complication, while it is much more rare than in scarlet fever, is of more frequent occurrence than was formerly believed.

There may be catarrhal involvement of the eustachian tubes and the formation of pus owing to the presence of the pus cocci, and other symptoms growing out of that inflammation. In like manner when it extends through the bronchial tubes to the air vesicles, we get bronchial pneumonia, in which we usually find a mixed infection. In fact, the broncho-pneumonia of measles is a more serious form of pneumonia, and is more likely to be followed by empyema than pneumonia under any other circumstances.

It is unfortunate that the laity look upon measles as a mild disease; because of this they grow careless, and many cases do not receive proper treatment. Not a few cases, when put to bed and given a liquid diet, recover without further treatment. But where the cough is severe and annoying, and prevents rest, I think something to allay the cough is entirely proper, and there is no better remedy for this purpose than paregoric, given in from ten to twenty-drop doses every half hour until the cough is relieved. Where the temperature is high enough to impair the integrity of the nervous system, as indicated by twitchings and occasional convulsions, remedies directed toward the relief of the temperature are entirely proper.

As stated before, the child should be kept in bed until the rash fades, then, if there is no complication, it may be permitted to be up and dressed. When it may go out of doors, will depend upon the weather and season of the year. I think it valuable for the practitioner to remember that when the rash fades, there is no complication, the temperature will go almost to normal. On the other hand, when the rash fades, if the temperature remains above one hundred, it is almost conclusive evidence that there is some complication, and this is most likely to be either otitis media or broncho-pneumonia.

The Surgery of Exophthalmic Goitre.

BY J. WARREN LITTLE, M. D.,

Clinical Professor of Surgery in the Medical Department of the University of Minnesota. Minneapolis, Minn.

In considering the surgery of a disease it is not enough to be able to say that such a disease is present in any case, but the various forms, typical as well as atypical, must be recognized, and in such cases selected for operation as surgical experience and judgment may dictate.

A good example of this is the old familiar theme of appendicitis; at one time the dictum was "operate as soon as the diagnosis is made." We know now that there are many cases in which this is very bad advice.

This same advice applied to exophthalmic goitre would be more disastrous because the operation is very much more difficult and only a few operators have cases enough to make them really expert. Then, too, there are certain inherent dangers that no amount of cleverness can avert.

It is generally considered that in exophthalmic goitre there is a hyperactivity of the thyroid gland, the same symptoms being produced in a normal subject by giving large doses of thyroid extract. Occasionally a case is met with in which the ordinary exophthalmic symptoms are present—and no enlargement of the thyroid exists. Such an atypical case came under my care about two years ago. A woman about twenty-five years of age consulted me on account of marked exophthalmia. She said she had consulted several oculists, who said her vision was perfect, and could give no reason for the condition of her eyes. At the time of my examination she had a normal pulse, no tremor, no enlargement

of the thyroid; in fact, her neck seemed smaller than normal. She had no symptoms of cerebral pressure or circulatory disease. I told her she had only one symptom of exophthalmic goitre, but that others might appear later and asked her to report occasionally. This she did. Several months later her pulse had quickened perceptibly and the usual restlessness began to be manifest. About a year from the time I first saw her, she was persuaded by her sister to accompany her to a dance in which she had joined with spirit. Near the close of the dance she was taken with tachycardia and her friends thought she would die before they could get her home, and well may they have been alarmed, for a patient with more tumultuous heart action and difficult breathing I have never seen, and I would not have been surprised to see her expire at any moment. Her neck, however, did not increase in size, and there was no enlargement of the veins. At the present time she is quite well and has returned to work. Exophthalmia has subsided, her pulse is less than one hundred and the tremor and restlessness much improved. About the only treatment she received was rest and avoidance of all excitement. Such cases as the above are likely not common, but when they are met they do not require surgical assistance.

Another class of cases in which operation should be avoided is described by Thompson, thus: Acute toxic thyroidism in which there is fever, excessive tachycardia, precordial distress, gastric and abdominal pain, vomiting, diarrhea, sleeplessness, perspiration, sense of suffocation, great restlessness, edema of the feet, in fact all the symptoms of toxemia due to thyroidism. Such cases if operated are likely to prove fatal at the time, or escaping that, within a day or two following. I have a case that will illustrate the one just described.

A young woman about twenty-three years of age had exophthalmic goitre, with most of the symptoms just given. She had a large, soft thyroid—both sides being about equally enlarged. For several months I visited her occasionally at her home, as she was too ill to come to my office. I kept her quiet, had the galvanic current applied faithfully, injected the gland with tincture of iodine and did some other fool things which included giving a good deal of medicine that did no good. Rogers and Beebe had not then given us their serum treatment. She did not grow worse, but I became discouraged and thought she ought to do better and so told her parents. We had several frank talks about operating. This lasted perhaps a month, the patient and parents leaving the time entirely to me. Finally, in an evil hour, I concluded she was in as suitable condition as I could get her and had her taken to a hospital. She was emaciated, weak and nervous, had marked tachycardia and a dilated heart. Being afraid to give a general anesthetic, I used Schlik's infiltration method. The girl died on the table a few minutes after starting the operation. There was some hemorrhage, but it was not excessive. The patient complained of being faint, became unconscious and could not be revived. The excitement and shock proved too great for the dilated heart to withstand. I take this to be a case of bad surgical judgment. To be sure, the patient likely would have died without an operation, but it is far better so than such a termination. Great harm comes in frightening those away who could be saved. Personally, I have never thought well of the kind of reasoning that goes something like this: "There is nothing to lose, the patient will die if you do not operate—medicine will not save him." This is wrong; there is a great deal to lose, unless there is hope of success based upon rational surgical principles. The great wonder is that surgery has so well withstood such abuse. Shepherd says: "I am of the opinion that early operations are the safest and the class of cases most likely to be benefited are not the most severe ones, but those in which the gland is more enlarged on one side than another, in which, in fact, there is more definite tumor formation, in which the gland is so excessively vascular, and in which the enlargement has preceded the symptoms of Graves' disease by months and perhaps years. These might be called cases of enlarged thyroid with a mild form of Graves' disease, in which the gland is soft, vascular and evenly enlarged throughout; here operations are

usually most satisfactory, the after results being decidedly good."

The surgery of this affection is comparatively recent, and no concerted action has been taken by surgeons as to what cases shall be accepted and what rejected for operation. Consequently, I do not hesitate to say that statistics as to mortality are of little value. In the milder forms the mortality ought to be slight. In the severer forms on the border line, where it is a question whether the patient can survive an operation, the mortality will be great. Therefore, when an operator reports a number of cases with a death rate of five, ten or twenty per cent, unless the history and details of each case is honestly and carefully given, you have no way of concluding whether that surgeon is superior, ordinary, or really bad. I am convinced that in properly selected cases there is no disease in which the results are more gratifying to both patient and surgeon. It is not uncommon to see a patient who, before the operation, was nervous and anxious, with a pulse of one hundred and forty, become quiet and comfortable, with a pulse around eighty, in three or four days following it.

The difficulty in performing the operation depends very largely upon the individual case. In a simple or cystic goitre that is large and firm and has a strong capsule, it is quite easy. In a small, soft gland, deeply set with a capsule almost as thin as a veiling, as is frequently seen in Graves' disease, it is a most tedious and difficult one. Here the gland must be teased or coaxed out of its bed; every slip must be seen so that you are at all times in command of the field, otherwise you will be confronted with most annoying and dangerous hemorrhage.

A difference of opinion exists among surgeons as to whether general or local anesthesia should be used. Personally, I prefer the former and favor giving a hypodermic of morphia preceding ether.

If a patient is in too precarious a condition to be given an anesthetic, the operation should be deferred.

The parathyroid glands and recurrent laryngeal nerve can be as well or better avoided by most operators. We are hearing recently a good deal about parathyroid glands and their functions, and it may not be amiss to give something of their anatomy, etc., as having great value when the removal of the thyroid gland is considered.

The parathyroid glands (about the size of orange seeds and brownish red in color) are two minute structures, which lie in more or less close relation to each lateral lobe of the thyroid body. They are apt to be mistaken for accessory thyroids, but in structure they are different. One, more constant in position than the other, is situated on the posterior aspect of the esophagus at the level of the lower border of the cricoid cartilage, and in more or less intimate relation to the posterior border of the lateral lobe of the thyroid body.

The second parathyroid body is placed either in close apposition with the lower border of the lateral lobe of the thyroid, or on the trachea, at a varying distance below it. The inferior thyroid artery intervenes between the two parathyroid bodies. The parathyroid bodies are composed of epithelial cells, and in structure bear a close resemblance to the anterior lobe of the pituitary body. It has been shown that the removal of the parathyroids from the cat is followed by very serious symptoms, and in two cases out of three death ensued in the course of a few days.

It is claimed on good authority that if complete thyroidectomy be performed and the parathyroids are left, that myxodema will not occur; but if they also are removed, myxodema will occur; again, if the thyroid is not removed but the parathyroids are removed, tetany will occur. Capsules of connected tissue completely separate the parathyroids from the thyroids. Considering their size and situation and value, I am sure we will use more care than ever before when making dissections in this region.

In preparing a patient for operation, the X-ray is said to reduce the size of the gland, at the same time making it more firm. The operation of sympthectomy has not grown in favor but has been almost entirely abandoned in favor of thyroidectomy. So also has the ligation of the thyroid vessels. Just how much of the gland it is necessary to remove depends

upon the individual case, usually at least one-half the gland to the isthmus, and sometimes the lower portion of the remaining side. The anatomy chiefly concerned in the operation, given as briefly as possible, is: the skin and platysma covering the sternohypoid, sternothyroid and omohyoid muscles. The arterial blood supply: from the superior thyroid, a branch of the external carotid. The inferior thyroid from the thyroid axis, and occasionally the thyroidima from the innominate, or from the subclavian or the internal mammary.

The superior thyroid vein drains into the upper and the middle into the lower part of the internal jugular, and the inferior thyroids into the innominate veins.

The anterior jugular commences near the hyoid bone from the union of several superficial veins from the submaxillar region. It passes down between the median line and the interior border of the sterno-mastoid muscle and at the lower part of the neck, passes beneath that muscle to open into the termination of the external jugular or into the subclavian vein. The nerve supply of the gland is from the sympathetic and the muscles are supplied from the loop of communication between the descendens and the communicans hypoglossi.

The motor nerve of the larynx, the recurrent laryngeal, lies in the space between the trachea and esophagus, near the inferior thyroid arteries, and can be avoided by leaving the posterior capsule of the gland, or hugging it very closely.

This hasty anatomical review is given merely as a reminder to the busy practitioner who may not care to look it up more in detail. The veins in this region have very thin walls and must be handled with unusual care.

In approaching the gland after the capsule is opened, the lateral veins should be seen and secured, the gland being carefully lifted up so that every point in the field is plainly visible. If the fingers are placed between the gland and its capsule and the gland hastily delivered, the lateral veins may be torn, and because of their close connection to the venous radicals, the bleeding is profuse. Dr. C. H. Mayo has shown that after the collar incision has been made and the skin and platysma in one piece dissected to a point above the gland, if the muscles covering the gland are to be cut, the section must be high, an inch and a half or two inches above the skin incision, to preserve the nerve supply, and to break the suture line so that the platysma and skin will not be fastened by adhesions into the muscle incision; the skin will thus be left free to glide over the neck as before the operation.

Report of a Case of Appendicitis, Pyosalpingitis and Ovaritis, with Adhesions Complicating Pregnancy.

BY GEORGE B. NORBERG, M. D.,
Professor of Gynecology in the University Medical College.
Kansas City, Mo.

I submit the following case, feeling that it merits some interest to both the general practitioner and the surgeon:

Mrs. C., about five feet four inches in height, weight one hundred and eighteen pounds; general appearance, fair; was brought to me in the early part of December, 1905, presenting the following history: Family history negative. Menstruated first time at the age of fourteen. Clerked in a store (being on her feet most of the time) for eleven years. She had none of the diseases of childhood except measles. Suffered greatly with dysmenorrhea from the beginning of her menstrual life until her first pregnancy. She was married at the age of thirty, and gave birth to a boy nine and a half months later. Her gestation period was normal. She expressed her feeling at the time of her first pregnancy by saying: "I felt better than I had for many years previous." Parturition was somewhat tedious, lasting thirty-six hours. She had a bilateral laceration of the cervix uteri and a perineal laceration, which was repaired promptly. She nursed the baby at the breast. Menstruated the tenth and eleventh months. She missed the twelfth month, and had other symptoms of pregnancy, such as nausea, soreness of breasts, etc. She weaned her baby

at this time. The object of her visit to my office was for a supposed pregnancy of about two and one-half months' duration, accompanied by severe pelvic pains, mostly referable to the right side. Constipation was a troublesome complication, no history of an infection could be obtained. She had rather indefinite knowledge of slight chills and some elevation of temperature, but ascribed these to the excruciating pains and nervousness which had almost rendered her an invalid.

On examination I found a capacious vagina, large, soft cervix, uterus retrodisplaced to the right side, connected with and bound down by a mass in that side which was so tender that it was palpated with difficulty. I might say without going into much detail that I was unable to determine whether I had a tubal pregnancy or some old inflammatory trouble in the tube to deal with. I kept her under close observation for about three weeks, and examined her several times. Her suffering increased, and she urged the exploratory operation, which I had advised. The urine analysis prior to the operation showed a small percentage of urea and albumen in considerable quantity. Frequent examinations in the last two months gave an entire absence of albumen, and the amount of urea is somewhat increased. I am unable to account for the disappearance of the albumen.

She was operated upon January 4, 1906, at the University Hospital. The usual median incision just above the pubis was made. On exploring the pelvic cavity the uterus was found to be large and soft (about the size of a three months' pregnancy), lodged behind the promontory of the sacrum, and to the right. The tube and ovary were bound down in one mass of adhesions, and the end of the appendix vermiformis adherent to the same. Near the proximal end of the appendix was a strong adhesive band almost dividing it. The distal end of the appendix was swollen about the size of the little finger, and later, when an examination was made, it was found to contain pus. After doing an appendectomy, the inflamed mass on the right side (containing tube and ovary) was removed. The tube was cut out from the cornu of the uterus, the uterine wound, and the broad ligament dealt with in the usual way. The abdomen was closed without drainage, as no pus had come in contact with peritoneal cavity. On macroscopical examination the tube was found to contain some pus. It was sent to a laboratory, but for some unknown reason was lost. With the exception of the first five or six days following the operation, when she had considerable trouble with flatus in the intestines, the balance of her stay in the hospital was so uneventful that it was scarcely interesting. She went home January 17th, thirteen days after the operation. Until about one month ago she complained very much of gastric disturbance, such as nausea. That has been overcome. She is now in her eighth month of gestation, and in fairly good health, the former distressing symptoms having almost entirely disappeared.

The significant facts in this case are:

1. That it was a surgical case.
2. It was very suggestive of ectopic gestation.
3. The appendicitis and pyosalpinx in this case occurring in conjunction with pregnancy was merely a coincidence.
4. The trouble, no doubt, originated in the appendix, and the colon bacilli gained entrance into the tube through old adhesions formed by a previously existing salpingitis. (This patient gives a history of having had painful menstruation from its beginning until her first pregnancy, which, no doubt, gave rise to extra uterine inflammatory trouble quite susceptible to infection; and the adhesions found were entirely too firm to be of recent formation.)
5. That cases demanding surgical interference can be dealt with without disturbing the existing pregnancy.

NOTE.—This case was reported about one year ago, and since the proof is before me for correction, I might add that she gave birth to a boy July, 1906. I have reports from her physician that her labor was normal, and that she is in the best of health.

General Conditions and Symptoms That Are Helpful in Diagnosis of Tubercular Joints.

BY A. E. BOOTH, M. D.,

Professor of Orthopedia in the Homeopathic Medical College of the University of Minnesota. Minneapolis, Minn.

1. *Insidious Onset.*—The tubercular inflammation is of low grade, and advance is slow unless the infection is mixed.

2. *Periodicity.*—This is observed in the periods of exacerbation and quiescence, lasting weeks or months, as the case may be. Oftentimes the patient during the period of quiescence feeling fairly well.

3. *Family Predisposition.* — This is seen in about twenty. per cent of the cases only. The general build of the patient, nourishment and environment must also be considered.

4. *Symptoms.*—Pain, almost always present to a greater or less degree; sometimes it is present only on motion. It is the cause of the night cry, and the muscular spasm about the involved joint.

Heat.— This means the character of the blood supply of the part, and its intensity will vary with the intensity of inflammation, and so in pure tubercular conditions is not nearly as great as in mixed infections. It is usually present, however, and can be determined by passing the hand from the well to the affected part, and noting the difference in temperature.

Swelling.—This is seen in edema and infiltration of the soft parts and enlargement of the bony parts; is sometimes more apparent than real from the atrophy above and below the affected joint.

Pain on Joint Pressure.—Is elicited by percussion. For example, in knee or hip by striking the heel of the affected extremity, also noticed in the jars in Pott's disease. Sometimes it is present in flexion or motion of the joint, and its absence during extension and fixation denotes synoval rather than bone disease.

Muscular Spasm.—The most important symptom yet. Noted in Pott's disease in the flattened and rigid spine. Observed in the hip, knee and ankle joint in their flexion and fixation. In fact, it is seen in any joint that is inflamed, and is nature's method of fixation for her cure. It is muscular spasm which produces the lumbosacral curve, so-called in hip disease when the patient is placed upon his back on a plane surface, and an attempt made to completely extend both thighs. In hip-joint disease it is relaxation of this muscular spasm which is the cause of the night cry. The muscles controlling the diseased joint becoming relaxed during sleep, permit slight motion, and this, in turn, pain, which is only to be increased by the muscular spasm it renews, bringing the parts sharply in contact.

Limited Motion.—This is double, caused first by spasm of the muscles controlling the joint, and, second, by infiltration in the soft parts of the joint.

It is seen where there is actual change in the contour of the parts, as seen in the angular spine of Pott's disease, in the fixation of almost any joint that is involved, and in particular is it of value in hip-joint disease, where almost never can we obtain abduction of the thigh on the affected side.

Atrophy.—The result of disuse and poor circulation is one of the later symptoms, sometimes more apparent than real, from the enlargement of the joint in question, but it is almost always present to a greater or less degree. We see it in hip joint disease in the wasted gluteal muscles. In disease of the knee both thigh and calf are involved, and is seen in most cases of long duration.

Deformity.—Here again we have muscular spasm, and actual fixation in the parts is accountable. For example, in the knee muscular spasm causes flexion, actual displacement of the tibia backwards, while at the same time change in contour of the condyles of the femur takes place, and the deformity is thus made worse. In Pott's disease we see it in the kyphos, and in hip-joint disease atrophy, flexion, rotation, etc.

Abscess.—This is a late manifestation and the case should not go to that point without diagnosis. Its presence, however, added to the above conditions, helps in diagnosis.

These are conditions and symptoms which can be applied to any joint in the

body; in their presence a diagnosis of tubercular disease may be made with reasonable assurance with very few exceptions, which can usually be differentiated with ease.

In virulent cases where muscular spasm is marked, or the symptoms severe, relief by traction usually means tubercular disease; non-relief means, probably, osteomyelitis.

Tuberculosis.

BY D. A. RICHARDSON, M. D.,

Professor of Chemistry and Toxicology in the Denver Homeopathic Medical College.
Denver, Colo.

Tuberculosis is an intensely contagious disease, acquired in various ways, never hereditary, runs a definite course, of pronounced characteristic symptoms, readily amenable to treatment, and in a great many instances subject to spontaneous cure.

If a mother subject to tuberculosis be sequestered from her children as soon as they are born, even in the presence of so-called predisposing tendencies, they may live to old age entirely free of the disease, never having been subjected to an infection.

In the consideration of its pathology, tuberculosis is of two varieties. The infection may take place upon the mucous membrane by way of the lymphatic system, by way of the ear or the nose or the mouth, to the cervical glandular system. Second, by the ingestion of the bacillus. The tubercle bacillus, which is the factor in all pathological changes in tuberculosis, is distributed through the economy by way of the arterial or venous systems, or through the stomach or intestinal tract. We will consider pulmonary tuberculosis in this paper.

It is not impossible that pulmonary tuberculosis should be of the miliary variety. The predisposing causes are long neck, flat chest and sloping shoulders.

The primary cause, is of course, the tubercle bacilli. The mechanical predisposing causes are the anatomical features just mentioned; these cause a mechanical functional inactivity which promotes the formation of tubercular tissue in this region (the apices).

The miliary form of tuberculosis follows the ingestion of the bacilli. One must recognize the fact that in a well-nourished person the bacilli themselves are the weaker factor; not every person who swallows tubercle bacilli, or infected chicken's livers, would suffer from miliary tuberculosis, but if the resisting power of the person is so depleted as to permit of the admission of the bacilli to the lymphatic system through the mesenteric machinery, miliary tuberculosis is sure to follow. Again we see that the lymphatic system is the main point of entrance. When the tubercle bacillus reaches that environment in which it may best survive, tubercular tissue forms and the destructive process begins. The destructive process is consumption. The process itself is tubercular, and this, to my mind, is the one distinguishing point between tuberculosis and consumption. The process may be extended from one or a large number of foci, such extensions, however, being subject to acute infections; thus we have, during seven years or more, many acute attacks or acute infections.

Pulmonary tuberculosis pure and simple closely resembles an ordinary lobar pneumonia. Its pathology is identical, both are characterized by cavity formation with pus and fibulated fibrin, both terminate in resolution.

The first positive symptom of an infection of tuberculosis is pain in the lung. It is not a pleuritic pain. This pain is at the site of the first infection, and is commonly mistaken for an attack of pleurisy. Auto-intoxication, and the first beginnings of degenerative process, accompanied by physiological phenomena of inflammation, and poisoning take place, with chill, fever, etc. The effort of the economy to get rid of these foreign bodies results in cough, at first dry, and later on mucopurulent, accompanied by more or less emaciation, weakness, loss of appetite, and, as the process extends, restriction of respiration on the affected side. As the tubercular process advances many chemical changes take place in remote parts of the body, notably the removal of calcium compounds from the bones, and

I believe the prolonged malaise of tubercular patients is due in the largest measure to this chemical change, or others which are similar, as the marked increase or diminution of sulphates and chlorides which would be noted at this time is caused by failure on the part of the economy to eliminate the normal amount of chlorides, and we have presented a chain of symptoms corresponding to the administration of sodium chloride in large amounts, according to the law of similars.

The tubercular process ceases when the infected area has been freed of the bacilli. The term general tuberculosis indicates an extensive infection; but tuberculosis tends to localize itself, hence we never have an acute general tuberculosis. It would seem that the tubercle bacillus, in its migrations or in its extension of environment, seeks to localize itself, and also seeks to confine itself in its latest environment. I have seen at autopsy the mediastinal glands a calcareous mass of tubercular tissue.

The results of tuberculosis are more serious in so far as the patient's comfort and well-being are concerned than is tuberculosis itself, and the chief pathology is resultant and not causative of the disease. I believe tuberculosis will one day be more amenable to treatment, and more easily cured than is diphtheria today.

[Written for the MEDICAL BRIEF.]

Pyothorax, Its Management, Etc.

BY A. DAVID WILLMOTH, M. D.,

Professor Surgery and Clinical Surgery Medical Department, Kentucky University. Louisville, Ky.

There is possibly no more interesting subject to the practitioner and surgeon than empyema. When we consider the large number of cases which follow croupous pneumonia, the interest of this subject to the general practitioner is understood. After the patient has been successfully carried through an attack of pneumonia, the surgeon is, in many cases, called to relieve a complication that is often more serious than the pneumonia itself.

Cases following pneumonia, where the infection is purely a pneumococcus, usually terminate favorably and leave few after-effects. It is a very fortunate case, indeed, where the accumulation in the pleura remains fibrinous or sero-fibrinous, and the patient is fortunate and the cases rare where the infection is purely pneumococcic, for there is constantly circulating in the blood and lymph streams both staphylococcic and streptococcic, particularly the first variety, and those find their way into the pabulum furnished them by the accumulation of serum in the pleural cavity, and they at once find a most excellent field for their activity.

If the patient is so fortunate, as stated above, to have only a penumococci infection, and the accumulation is small, it may often be cared for by nature; however, most cases of this variety will require surgical interference, if nothing more than a paracentesis, removing the pus in a mechanical way. The number of cases that recover after simple paracentesis is rather large, considering how many have an accumulation in the pleural sac. Drainage can be maintained by the introduction of a tube. This tube can either be of rubber, or what has served a most valuable purpose in my hands, a gutta percha tracheotomy tube, just long enough to reach inside the sac and fitting snugly against the side, and maintained in place by adhesives. Or, if a number of aspirations have been made, nature is then able to care for the remainder, and, finally, the patient makes a fairly successful recovery.

Unfortunately, in a large number of cases these simpler methods have been tried before the surgeon is called in, and he has more often to deal with a true pyothorax as the result of infection, most often by the staphylococci. In all such cases, whether of infection following pneumonias or through those following trauma, a more radical operation must be done.

The simplest measure which will be necessary in these cases will be an incision over the rib that will permit the surgeon to resect a small portion to allow for drainage, and through this he must maintain drainage for a number of days. This operation is, usually, sufficient, and

the surgeon is required to do no more. If, however, the case is one of infection following trauma, where the pleura has been wounded, and a direct infection has occurred, either into small amounts of serum or into the blood clot that has accumulated in the sac, there is usually more required than the above operation. Resection in these cases should be larger than in the other variety, for the drainage must be maintained for a longer period. The first thing to be determined is whether we are dealing with pus in the sac. If the case be seen by the surgeon at the start he can easily determine this by a simple hypodermic syringe. The patient, of course, has fever, elevation of the pulse, and these, with the history of the case, makes diagnosis comparatively easy. The next question is as to the size of the cavity that he is dealing with, whether it has been walled off, or whether it involves not only the sac, but the lung itself. This can only be determined at the operating table, and where the surgeon has opened up the pleural sac and is dealing with large amounts of pus, after he has taken precautions to allow it to escape slowly, to prevent the detrimental effects that would follow the evacuation of large amounts of fluid from any of the cavities. He should then inspect the cavity with a finger or sound of some variety to determine the size of the sac that he is dealing with. If it is walled off and is not too large, and is an acute case, irrigation with an antiseptic saline, such as the normal saline solution or boric acid, will gradually close up the sac, and the drainage that escapes from time to time will gradually grow less and less, until finally the sac is closed by the parietal and costal layers of the pleura becoming adherent. This is the simplest manner in which the damage can be repaired, and is far better than to allow the pus to remain in the sac, no matter how small the amount.

In some cases, where resection of the rib has been done and drainage maintained, the sac still refuses to close. The case has, perhaps, been allowed to go on until the patient is emaciated from the suppurative condition and the constant drain of the system, to say nothing of a possible secondary infection of the tubercle bacilli in the lung tissue. The surgeon should, therefore, interfere in the case just as early as he is assured that nature will not be able to close the sac; he then must aid her by bringing the two layers of the pleura together, where the pulmonary layer can not expand and reach the costal layer. In other words, the Estlander operation, or a modification of it, must be done. He must determine in his mind the size of the sac that nature is contending with, and then must resect enough ribs to allow the layers of the pleura to come together. Personally, I am partial to the U-shaped incision, which allows the surgeon to have ready access to as many ribs as he finds necessary to remove. The slight amount of hemorrhage that occurs in the elevation of the flap is usually easy to control, unless accidentally the costal artery is opened. If this artery be opened during the removal of the flap, or in the removal of the periosteum from the ribs, it is easily controlled by resecting the area along which the artery runs, and then dealing with the artery direct. After the hemorrhage has been controlled the surgeon should begin the resection of the ribs, and he should always be sure that he removes as many ribs as over-lie the cavity beneath. It is far better for him to remove one rib too many than to allow one to remain which holds the pleura slightly above the layer beneath, for if this happens the efforts at closing the sac will be thwarted; the two layers of the pleura still remaining separate at this point, and a small cavity remaining, which will constantly secrete more or less material, and the brilliant operation that was done at the table will fail to be a complete success. After the ribs have been removed the question to determine is whether or not the costal layer of the pleura is to remain or to be removed. If it is purely a pyogenic infection the pleura should be allowed to remain. On the other hand, if it is a case where tubercular infection has become engrafted with the pyogenic, and the costal layer shows the tubercular nodules, it is then best to remove all that is involved, and to cover the layer beneath with the flap that has been elevated.

While this may seem a radical operation, yet it offers a hope, and a very great

hope to a class of cases that are more or less hopeless unless relieved in this manner.

There is still another class with accumulation in the pleural cavity, and concerning which there is some question regarding the treatment to be instituted by the surgeon. I mean those cases of tuberculosis in which there is an accumulation in the pleural sac that interferes with the patient's breathing, and is more or less a menace to life. I can see no reason why an accumulation in this class of cases should not be dealt with as in the acute form, believing that even the accumulation is, in a way, not highly toxic; that where it is removed aseptically, you relieve the patient by ridding him of material that nature can not care for herself. So, even in those cases of pulmonary accumulation, I would still favor the resection of one rib, at least, and a thorough drainage of the cavity, believing that the patient can not fail to be benefited by the operation.

Vital Activity of Cell Life.

BY WILLIAM L. WARRINER, M. D.,
Professor of Physiology in the Kansas Medical College.
Topeka, Kan.

Herbert Spencer defines life as a continuous adjustment of internal relations to external relations. All processes of the body are vital, to be explained along natural phenomena, like chemical and physical processes. Life is maintained, I believe, by special vital activity of the cells. While little has been written on this subject, I think it is pretty thoroughly agreed that certain processes can only be explained through vital activity of the cells of the body.

It is not too much, perhaps, to say that the cells of the alimentary and digestive tracts have a mind, a consciousness, in their method of selection, retaining what is needful for the support of the body and eliminating all waste products. The whole process of digestion hinges upon the special vital activity of the cells in physiological secretion and excretion. I believe that by natural selection nourishment passes from the system to the blood and through the blood to the lymphatic system, where it is assimilated by the tissues. The food is not merely ground up into a soft pulpy mass and digested, but passes through the alimentary tract, and by the vital action of the cells lining that tract, such portions are selected as are needed by the economy.

This is certainly true of the cells of secretion, and why not those of excretion? For instance, if you examine the cells in the glands of the stomach, they will appear identical in structure, both anatomically and histologically, yet part of them are secreting pepsin, part rennin, etc., etc., showing the power of selection there. In other words, a physiological selection is going on at all times. Necessary juices are secreted, differing in quality, yet the cells are practically alike.

The juices of the stomach are secreted in the same way, by natural selection, through vital activity of the cells. Gastric juice, saliva, tears, in fact, all secretions of the body, are manufactured through the vital activity of the cells. Lymph is probably formed in the same way, by the selective action of the cells lining the blood vessels.

In the digestive tract, we have the selection of certain classes of foods, and their absorption, and this selection can not be explained by osmosis; as a proof that absorption is performed in this way, we know that in ordinary osmosis, albumen is not diffusible, but in this process of absorption through the cells, it is readily diffusible.

All through the processes of life there is a physiological selection going on, and the cessation of this unconscious selection in any portion of the body is followed by disease. For instance, excretion, which is carried on through the same vital activity, ceases, in the kidneys; the cells are destroyed and the destruction of them we call nephritis or Bright's disease. The products are no longer retained by the activity of the cells and we find in the urine sugar, albumen, etc. This subject is one of vital interest and at present very little understood, or rather, I should say, not very clearly explained.

A Note on the Relation of Valvular Lesions of the Heart to Life Insurance.

BY ALLISON MAXWELL, A. M., M. D.,

Professor of Clinical Medicine and Diseases of the Chest in the State College of Physicians and Surgeons; Medical Director of the State Life Insurance Company of Indianapolis. Indianapolis, Ind.

Most of the life insurance companies as a rule will accept a man for insurance with a purely functional heart murmur, provided he is in good health and his personal and family history are good. Some companies will accept a man for life insurance with an organic heart murmur, with some hypertrophy of the heart, if there is proper compensation and the personal and family history are good. However, the insurance granted to such an applicant is not excessive and is of the ten, fifteen or twenty-year endowment type usually, because he is regarded as an impaired risk.

Frequently the lesion which is most common is mitral regurgitation, and of all valvular heart lesions this is the least harmful. Applicants suffering from this form of lesion are more likely to live out their life expectancy than with any other form of valvular trouble.

This last statement must be qualified:

1. By the man's occupation. If this is a quiet vocation, without mental excitement or undue muscular exertion, he may be an acceptable risk.

Again, a man fifty years old, with mitral regurgitation, or any other heart murmur, can hardly be acceptable because of his age. While one twenty-five years old might be acceptable on the twenty-year endowment plan, or with a lien upon the policy.

A man with good past habits, who has a heart murmur, may be a fair risk for insurance, while a man with similar lesion, who drinks or who dissipates in other ways, will shorten his life and be undesirable.

A man with an aortic regurgitation, I do not think would be an acceptable risk on any plan, for he may die suddenly, although Babcock states that when this is due to endocarditis, if compensatory hypertrophy has occurred the disease may be borne for many years; but when compensation begins to fail in aortic regurgitation, it is doubtful if it can ever be restored as in mitral regurgitation.

Of course, any disease complicating valvular trouble, as Bright's disease, or affections of other vital organs, would make a risk very undesirable.

However, write as much as we will, and deliberate as much as we may upon these cases of valvular lesions of the heart, it is probable the exception rather than the rule that life insurance companies will take as acceptable risks on endowment or any other form, those applicants who have an organic heart murmur.

Diseases of the Breast.

BY ALFRED DE ROULET, B. S., M. D.,

Chicago, Ill.

Formerly Professor of Surgery and Diseases of Women in the Medical Department of Trinity University.

II. THE PATHOLOGICAL HYPERTROPHIES.

Diffuse virginal hypertrophy of the breast is a comparatively rare, though frequently described, condition. It occurs most frequently in women from fifteen to thirty years of age. The onset is insidious and the development slow. As a rule, the growth is unaccompanied by pain, although tenderness may be present. Both breasts are usually affected, but not necessarily to the same degree. The enlargement is due to a uniform overgrowth of all the tissues rather than the excessive development of any one particular element.

As the breast enlarges it projects sharply from the chest wall, presenting an appearance similar to that of the developing breast of a woman pregnant for the first time. As the growth continues the breasts become pendulous, the superficial veins become dilated, the areola enlarges, but the nipple becomes less prominent, not from atrophy, but on account of the disproportionate development of the surrounding tissues. As a rule, the skin remains perfectly normal and free from adhesions to the underlying

structures. In cases where the enlargement is extreme, the more dependant portions of the breast may be more or less edematous.

Fig. 1. Diffuse Virginal Hypertrophy of Breast

Aside from the deformity incident to the condition, the enlarged breasts may cause considerable annoyance and discomfort on account of their size and weight. When the hypertrophy is excessive, respiratory difficulties may be expected.

The diagnosis is based on the gradual uniform enlargement of both breasts, with complete absence of skin or lymphatic involvement. Inflammatory symptoms are never present. On palpation the sensation is that of normal breast tissue, no thickened or indurated areas being perceptible. The manipulation incident to an examination ordinarily occasions neither pain nor discomfort.

In the two cases which I have seen, the first, a rather slender German girl of nineteen presented the following history: When fifteen years old both breasts began to enlarge, the growth being rather more rapid on the left side. During the first few months the development was quite rapid, then continued rather more slowly until she was seventeen, since when there has been no noticeable enlargement. At no time has she suffered from pain, and at no time has her general health been affected in the slightest degree. She has never had any menstrual disorder of any kind, and the pelvic organs at the time of examination were apparently in excellent condition. The second case was that of a young Jewess, twenty-four years old and unmarried. While both breasts were affected, the right was considerably larger than the left. The breasts were firm and elastic in consistence, but distinctively sensitive to pressure. The patient stated that neuralgic pains in the breast were of comparatively frequent occurrence. In this patient menstruation was irregular, occurring at intervals of from three to five weeks, the flow lasting seven or eight days, and accompanied by considerable pain. No abnormality of the pelvic organs could be detected, however. In both cases the treatment was limited to palliative measures, and the results were about as expected.

Senile parenchymatous hypertrophy of the breast has long been recognized by

Fig. 2. Diffuse Virginal Hypertrophy of Breast

surgeons and pathologists and has been repeatedly described under a vast medley of names, as cystic disease of the breast (Bryant), hydatids of the breast

(Cooper), intra-acinous cystic epithelioma (Reclus), chronic cirrhosing mastitis (Billroth), periductal mastitis (Delbet), chronic cystic mastitis (Koenig), cystadenoma (Schimmelbusch), senile atypical parenchymatous hypertrophy (Bloodgood), abnormal involution (Warren), fibrous and glandular hyperplasia with retention cysts (Whitney), etc. This confusion in nomenclature may be reasonably attributed to the varying gross and microscopic appearances of the condition at different stages of its growth or development.

The disease is distinctively one of the senile or declining breast, and is observed most frequently between the ages of forty and fifty. In Greenough and Hartwell's analysis of thirty cases, the youngest patient in this series was twenty-five years old, the oldest fifty-two, the mean age forty and four-tenths years. This shows the age incidence to be a trifle lower than the age at which menopause is commonly expected. Occurring as it does at the age when cancer is most frequent, it is of the greatest importance to differentiate the two conditions.

As to the exact nature of the pathological changes, it should be remembered that a certain amount of cyst formation occurs normally, as a result of the obstruction of the ducts and acini during the involution of the senile breast, but the line where the physiological process stops and the pathological begins, is by no means clearly defined. Inasmuch as the mammary epithelium is notoriously a tissue of unstable equilibrium, the cystic changes just mentioned often lead to a secondary epithelial proliferation which, in the majority of cases, does not go beyond the stage of hyperplasia, but which may, and in certain cases does, go on to cancer formation. The pathological process is essentially hyperplastic in character, rather than inflammatory or neoplastic. It must not be forgotten, however, that while the disease in its early stages is perfectly benign, in the late stages at least one case in every ten becomes malignant.

The clinical picture of senile parenchymatous hypertrophy may be summarized briefly as follows: An irregular indurated mass with vaguely defined margins is found either diffusely involving the entire mammary gland, or more or less definitely localized in some particular portion. In some cases an irregular "corded" feeling of the gland, with scattered indurated spots or nodules, is all that can be detected on palpation. When the disease is localized, the indurated area is most frequently found in the outer hemisphere of the breast, and is found occasionally in the lower hemisphere and in the region of the nipple. The inner hemisphere, and especially the inner upper quadrant, is rarely the seat of the localized process. Either or both breasts may be affected, the condition being bilateral in rather more than half of all cases. Cysts are frequently observed and may be of considerable size. When cysts of any size are

Fig. 3. Senile Parenchymatous Hypertrophy of Breast.

present, the borders of the indurated areas are much more sharply defined than they would be otherwise. The mass is ordinarily of very slow growth, except when large cysts are present, when the development may be quite rapid. Adhesions of the mass to either the skin or the fascia do not occur, and the axillary and supraclavicular lymph glands are not involved. In a few cases, a watery discharge from the nipple, followed by a temporary diminution in the size of the tumor has been noted. In the cases where this occurs, the enlargement is usually situated immediately beneath the nipple, and it is possible that the discharge depends more on the location of the cyst than upon its character.

The prognosis in any given case of this disease when untreated is a matter of great uncertainty. The disease may advance to a certain stage and then remain quiescent indefinitely. Suppuration of the cysts is ocasionally observed, and in very rare instances, the induration has subsided spontaneously. Cancer develops in from ten to twelve per cent of all cases.

The line of treatment indicated in these cases is clear. In every case complete removal of the mass is indicated not only on account of the tendency of the growth to become cancerous, but because its presence may conceal or mask the development of an entirely independent malignant disease. In cases where the indurated area is small and the presence of well defined cysts renders the diagnosis certain, delay in operating may be excused, but extension of the process imperatively demands immediate operation. The operation most suitable for this condition is the subcutaneous resection of the mammary gland, the technique of which will be considered in a subsequent paper. Should there be any evidence of malignant degeneration, the radical operation should be performed in the same manner as for any other breast cancer.

In any case, after operation, the patient should be examined by the surgeon at gradually lengthening intervals, for a period of at least three years, to insure the early detection of a possible recurrence.

The Treatment of Rheumatic Conditions.

BY J. W. HIGGINS, M. D.,

Professor of Pediatrics in the Denver Gross Medical College. Denver, Colo.

The treatment of rheumatic subjects involves a study of the individual, climate, environment, occupation, and more especially the diet. Aside from medicinal treatment, it should always be remembered that the general system of the subject of any of the forms of rheumatism is overtaxed. This applies especially to the liver, kidneys and lymphatic system, which are suffering from engorgement. The channels of elimination being obstructed, our first object should be to stimulate secretion and open up the avenues of escape.

The intestinal tract, the laboratory for the manufacture of toxins, is many times responsible for the development of an attack. In evidence of this there is the presence of indican in the urine, which is proof of septic decomposition in the intestinal canal.

To Dr. W. H. Porter, of New York, is due much of the credit for so forcibly calling our attention to the importance of recognizing this condition. The rheumatic condition is but one of the many phenomena arising from a disturbed nutrition from auto-intoxication, having their source in the digestive system, and any treatment that does not recognize a disturbed condition of the digestive system must meet with failure.

In the way of medication, one of the most efficient drugs is calomel, given in liberal doses of from one-half to five grains, combined with some active cathartic, as compound extract of colocynth, to stimulate peristalsis. The salicylates may be given in varying doses of from five to ten or fifteen grains for the first twenty-four to forty-eight hours, until the temperature has been controlled, which is an evidence of the removal of the septic material and the stoppage of its manufacture. Hepatic stimulants and tonics, and a careful supervision of the diet, giving only foods that tax the digestion the least and at the same time contribute the most to the general nutrition. For the

first, strychnia, given in doses of from one-thirtieth to one-twentieth of a grain every four to six hours, to stimulate circulation and aid elimination and tone up the nervous system. Caffeine, by dilating the arterioles, aids greatly toward elimination, and is one of the most efficient remedies. It may be given in doses of from one to three grains every four to six hours.

The diet should be regulated according to the needs of the system, and the capacity of the digestive organs. Among the foods best adapted to this condition are, first, meats, eggs, milk, white bread, butter; in fact, good, plain, easily-digested foods, excluding all sweets, fruits, dressing and any foods that have a tendency to overtax the digestion, especially the small intestines. The amount of food given to be regulated by the capacity for assimilation.

Early Recognition of Orthopedic Deformities.

BY J. W. STEVENSON, M. D.,
Surgeon in Charge of the United States Marine Hospital.
Cincinnati, O.

There are few deformities which we can not prevent if the case is seen early enough. The majority of the deformities of childhood are seen at birth. Congenital club foot, diseases of the spine, bow-legs, knock-knees, occur soon after birth and are first seen by the family physician. It is he who is responsible if the child does not early receive proper treatment. Hip joint disease occurs later in life. There should never be a club foot, a hump back nor bow-legs nor knock-knees. All these conditions respond promptly to early and proper treatment. In hip joint disease the child is born with a tubercular joint. Pain and crying are the first symptoms, which are too often neglected. The child limps, perhaps he falls, and not infrequently the family physician will pronounce the pains to be rheumatic. After futile treatment, an abscess of the joint has formed and the mischief is done, and a radical operation is imperative.

The family physician is the man who has it in his power to prevent practically all the deformities of mankind. And until he is willing to recognize his shortcomings and refer his little patients to the proper specialist, just so long will we see such deformities. The early recognition of orthopedic cases is the one important feature. When a child complains of pain in his leg or back, and cries almost continually, it is the business of the family physician to discover the cause. There is something radically wrong with such a child. If treatment is delayed until the deformity is well advanced and the condition becomes chronic, the specialist is at a disadvantage when the patient finally reaches him. In my practice I can recall case after case which might have been cured in the early stages, but who came under my notice after many years of suffering and deformity. One such case will suffice for illustration:

A little girl, eleven years of age, was referred to me for treatment. She had congenital club foot, and was treated by the family physician until six months ago. This physician pronounced her condition paralysis, and when she was old enough to walk fitted her with a heavy steel brace, which she had worn constantly for eleven years, the last brace she wore weighing at least twelve pounds. When she came under my care I instituted the plaster of paris treatment, and at the end of six months she is able to wear a shoe, walks perfectly flat-footed, and the braces worn for eleven years are completely discarded. She walks perfectly well, and now only suffers from the atrophy of the muscles from the long disuse of the leg while wearing braces. The only essential difference between the shoe she wears and the ordinary one, is that the shoe is built up a little on the outside. From the present appearance of her foot and her gait no one would suspect a former case of club foot. Every bit of the suffering and inconvenience endured by this child could have been avoided if the practitioner who had attended her from birth had advised proper treatment.

Much has been said and written on this subject, but it is not until the practitioner is generous enough, and human enough, to know when he is not curing a disease, and to send the little patient to a specialist, that we shall hear the last of it.

La Grippe.

BY W. S. GIBBS, M. D.,

Professor of Principles and Practice of Medicine and Clinical Medicine in the College of Medicine of University of Nebraska.
Omaha, Neb.

La grippe, or, as it is sometimes called, the influenza, has been in our midst for the past seventeen years, making its appearance here as an endemic disease after having encircled the globe; appearing first in Bokhara, extending over Asia and all Europe, traveling across the Atlantic, and commencing its ravages in America. It rapidly spread over this country, attacking thousands upon thousands. The disease is caused by the bacillus of Pfeiffer, and is the primary factor in the production of innumerable conditions. We have no means whatever of checking its onset, and we are as absolutely helpless to prevent its visits. I regard it as the most important of all infectious diseases, not excepting tuberculosis or rheumatism. There is no tissue, organ or fluid of the body that may not be infested by this germ. It has been found in the blood and all the tissues, in the mucous membrane, and in the nerve structures.

So far-reaching has been its influence that I think I am safe in saying that it has caused a greater variety of disease, more varied in their action, than all other infections combined.

When we consider that its effect on the nervous system is such as to cause violent insanity; a physical prostration that requires our best efforts to overcome, an extremely high or a subnormal temperature, it seems to me that the importance of this disease should be more thoroughly appreciated. And the physician as the conservator of the health of the people, should feel the responsibility of enlightening the laity.

Too often la grippe is regarded as a mere cold, until followed by complications which render it fatal. Physicians seem to tire of pronouncing the name of this disease, and prefer to call the case one of pneumonia, bronchitis, rheumatism, pleuritis, or gastro-enteritis, when it is really la grippe, and if treated accordingly, the patient would be saved serious trouble.

One of the commoner symptoms of la grippe is pain, followed by swelling, although some of our best authors contradict this statement. I recall two cases illustrating the importance of diagnosing this symptom. A child five years old was suffering with a swollen arm; very painful. Temperature 105°. There were no other pathological conditions outside of the pain, fever and swelling. I diagnosed the condition as la grippe with muscular inflammation. The administration of appropriate remedies relieved the little patient in a few hours, and in twenty-four hours the inflammation had practically disappeared. Despite the view of some well known authors on this subject, I believe that many cases show swelling and inflammation of tissue, and in some instances peri-articular.

I recall one case, that of a young lady who had been treated for weeks in the hospital for what the physician called rheumatism of the ankle. She had continuous fever with great prostration. Investigation of the case revealed the fact that the inflammation was caused by the bacillus of Pfeiffer. She was treated accordingly, and recovered in a week after having been treated for rheumatism several weeks.

There is no question but that the pneumonia produced by the bacillus of Pfeiffer is not only different from that produced by the pneumo-coccus, but requires entirely different treatment. I have seen many cases of gastritis, even when treated by the best methods, fail to respond, because of the non-recognition of the presence of la grippe. I have seen these cases promptly respond when the proper remedies for la grippe were employed. This applies to nervous conditions induced by la grippe, insomnia, somnolence, etc. Treated directly without taking the underlying cause (la grippe), into consideration, there can be no improvement. Grippe is not a self-limited disease, unless limited by death.

I should like to call attention to the importance of early diagnosis of la grippe in puerperal women. I have seen four such cases, and they were all serious. It

is imperative to make a prompt diagnosis between la grippe and septicemia.

The patient suffering from la grippe should be put to bed, in a warm, well-ventilated room. I believe that ventilation is more essential in this disease than in any other. In a hospital these cases should be isolated, if possible. Liquid food and warm drinks may be administered every two hours, except, perhaps, at night, when some of the feedings may be omitted.

There is no specific in the way of medication, and each case requires individual treatment. I think it a good plan to administer calomel, about one grain, with some saline, every four hours, until the bowels are thoroughly evacuated. Even if there is gastro-enteric trouble I believe the calomel is still useful.

Quinine is an important part of our treatment in la grippe. In most cases it is best administered in three-grain doses every three or four hours. In many cases I prescribe strychnine, and often digitalis. the former as a tonic, and not as a curative agent. In cases where the temperature is subnormal or low, I often administer asafetida every three hours, keeping up the strychnine and digitalis. The aromatic spirits of ammonia is useful as a stimulant and expectorant.

I regard the coal-tar products as very useful in this disease. Salol is good.

Artificial Respiration.

BY J. HARVIE DEW, M. D.,

Fellow of the Academy of Medicine; Member of the Medical Society of the County of New York; County Medical Association; Alumni Association of the Charity Hospital; Physicians' Mutual Aid Association, Etc., Etc. New York City.

The subject of artificial respiration in asphyxiated conditions, has received but little attention within the past few years, and yet it is one of great importance whenever an emergency arises requiring its use.

The old Sylvester method still stands at the head of the list, for the simple reason that it is known to every physician; it is probably the most ready and available method which can be promptly resorted to in adult asphyxias from almost any cause. And at one time it was regarded as the best method in cases of asphyxia neonatorum. But where the physician is called upon to use any special method once in the adult, the obstetrician will have occasion many many times in cases occurring at childbirth.

Nearly all of the works on obstetrics that have been published within the past decade have advocated Schultze's method as the most reliable, and have described it in detail. This, I believe, is entirely due to the fact that authors are not thoroughly familiar with the practical use of the newer "Dew's Method."

On March 11, 1893, I published an article in the New York *Medical Record* which had been read before the Academy of Medicine, "Establishing a New Method," etc., which I had devised as far as I knew, and practiced, as had many of my professional friends, since 1870. This has been called "Dew's Method." It possesses far greater utility and many advantages over any other method thus far proposed.

There is not a desirable feature in the Schultze method that is not provided for in this, and all of the objectionable ones are completely overcome, while at the same time it possesses many practical advantages which the Schultze method can not supply.

My directions for practicing this method are: First, to blow up the lungs by a mouth-to-mouth inflation and then to grasp the infant with the left hand, allowing the neck to rest between the thumb and forefinger, the head falling far over backward, straightening the mouth with the larynx and trachea, thereby serving to raise and hold open the epiglottis, the upper portion of the back and scapula resting in the palm of the hand, the other three fingers to be inserted in the axilla of the baby's left arm, raising it upward and outward.

Then with the right hand, if the body is large and heavy, grasp the knees in such a way as to hold them with the right knee resting between the thumb and forefinger, the left between the fore and middle fingers. This position will allow the back of the thighs to rest in the palm of the operator's hand. If the infant is small and

light it will be found more convenient and easier to hold it in the same way by the ankles instead of the knees, allowing the calves instead of the thighs to rest in the palm of the hand.

The next step is to depress the pelvis and lower extremities so as to allow the abdominal organs to drag the diaphragm downward, and work the left hand to gently bend the dorsal region of the spine backward; this enlarges the thoracic cavity and produces inspiration.

Then to excite expiration, reverse the movement bringing the head, shoulders and chest forward, closing the ribs upon each other, and at the same moment bring forward the thighs, resting them upon the abdomen. This movement arches the lumbar region backwards, and so bends the child upon itself as to crowd together the contents of the thoracic and abdominal cavities, resulting in a most complete and forcible expiration. (For figures illustrating see New York *Medical Record* of March 11, 1893.)

While the movements in this method are powerful ones, the operator can, by his manipulations, perform them without shock, and render them as gentle as he pleases. This it is quite impossible for him to do in performing the Schultze method.

Every obstetrician will find that by far the most frequent cases of suspended animation are not extreme cases of asphyxia, and yet when the infant has failed to breathe, and does not respond to the ready methods of excitation, such as spanking, rolling from side to side, sprinkling water upon it, etc., the use of some form of artificial respiration will be of the greatest assistance.

Under such circumstances I at once clean the mouth, inflate the lungs, and use my method, with most prompt and satisfactory results.

The advantages of this method are: That it is most efficient in all cases where artificial respiration, in asphyxia neonatorum, is indicated.

That its movements are easy and can be quickly resorted to at any moment, and anywhere.

That while its inspiratory movements will be found, by experience, to be as efficient as that of any other method, the expiratory movement is far more complete and satisfactory than any of them.

That nearly, if not all of the air drawn in can be expelled. This is most important.

That owing to the force, and at the same time to the absolute control which the operator has over the expiratory movement, he is able to compress the contents of the thoracic cavity to just exactly that degree deemed by him wisest and best, thereby favoring not only the respiratory process, but the proper emptying of the heart and large blood vessels, which can only be forward and in the right direction, thus most advantageously favoring, improving and hastening the general circulation.

That the method can be employed before the cord is cut, when it seems important to save as much blood as possible to the infant.

That, if thought best, the movements can be kept up while the infant is immersed up to its chin in hot water.

That by elevating the buttocks and depressing the head and shoulders, the expulsion of mucus can be effected as in the Schultze method.

That for alternating with other methods it possesses peculiar advantages affording great relief to tiresome positions in protracted cases.

That it possesses all of the advantages of the Schultze method and none of its disadvantages.

Finally, that the method is prompt, reliable, easy to perform, and perfectly safe.

Some Unrecognized Forms of Neurasthenia.

BY LINCOLN GRAY TAYLOR, M. D.,

Professor of Neurology in the Medical Department of the University of Kansas.

Kansas City, Mo.

These cases are not recognized usually by the attending physician, for the reason that they are almost symptomless. No particular symptom or set of symptoms may accompany the condition, except, perhaps, a mild prostration, which may be mistaken at a casual glance. A diagnosis is reached rather through the history of

the patients, watching them a few days, etc. It is generally a history of overwork, weariness, etc., which is given the attending physician. One case may exhibit a definite set of symptoms, another may be entirely different or practically without symptoms. The two cases following are quoted as good examples of this alarmingly frequent condition—which is too often overlooked and wrongly treated.

I was called to see a young woman suffering from prostration, headache, loss of appetite, and who claimed to be too ill to leave her bed. She gave the following history: For the past three months she had been complaining of feeling badly, and unable to attend to her duties as bookkeeper in a downtown office. She grew better, then worse, in a few days, and had a general feeling of being "run down" and exhausted on slight exertion. On examination I found that she had some temperature (101° F.) and diagnosed a simple case of neurasthenia. Her bowels were regulated and she was put to bed. I told her she would not be able to return to her office for at least two months. She will remain in bed for two weeks, then she must go to the country to recuperate.

Case 2. I was called to see a woman who had had attacks of fainting. I found a strong, robust woman of forty, who had acted as housekeeper for her father and mother. Her family history was good. I was informed that she had overworked herself during the past few days. The family had been moving and, as no help was obtainable at the time, the two women did much of the work. On examination I found the heart was beating very irregularly. I instructed the woman to remain in bed two days until she was thoroughly rested, and to be careful not to exert herself too much after returning to her work. A week later I was sent for again. The same thing over again, palpitation of the heart, faintness, waking in the middle of the night, thinking she would die of suffocation, and this in a woman who was not naturally nervous. I said to her: "I have underestimated your case, you must go to bed and stay a week." She went to bed and stayed a week and got up feeling a great deal better, but at the end of another week she sent for me again. Further questioning elicited the information that her recent attacks had not been due to the over-exertion incident to moving, but to years of overwork. It appeared that she had acted as nurse to her father during a trying illness lasting six weeks. Just one month afterward her mother became ill and required nursing for three weeks. Before having time to rest from the extra exertion, preparations were begun for her sister's wedding—months of sewing, etc.—and finally, after the wedding was over, and getting the house in order again, she had the responsibility of the moving which had recently been done.

Then, for the first time, I was able to estimate the case; that instead of being ill from the results of a few days' overexertion, she had been exhausted through years of over-work and responsibility. I said: "Young woman, you must go to bed for six weeks. Four of those weeks to be spent in bed, the remaining two from bed to chair and from chair back to bed." At the end of that time you must go away on a visit for six months, then you will be quite well. All of which was duly carried out and she came home perfectly well.

The point of this story is that we must recognize the underlying neurasthenia and treat the case accordingly. The patients must be given a sufficient amount of rest and time for relaxation.

I make a diagnosis of neurasthenia in many cases milder than the two reported, which will recover in two, three or four weeks. They may be simply in a run-down condition and respond quickly to rest and treatment.

A physician should give a definite prognosis in these cases, setting forth the point of time and telling the patient just when they will recover. As soon as their minds are set forward to a definite time of recovery they will be resigned to knowing they will be sick two or three months, instead of weeks, and this will save them from delay and discouragements.

The treatment is indicated by the manner in which I handled the foregoing cases. They should be put to bed absolutely and approach as nearly as possible the Weir Mitchell method of treatment—

no visitors, good, nutritious diet, possibly a tonic, etc. The first few days after putting the patient to bed they will grow restless, but these patients must be handled with an iron will. The physician must be positive in his diagnosis and equally positive as to his treatment. Hesitation in the care of these patients is disastrous. I state my prognosis positively and the treatment must be carried out with equal positiveness if good results are to be expected. If these cases are not treated and kept in order they will become a burden not only to themselves but to those around them.

[Written for the MEDICAL BRIEF.]

Prevention of Tuberculosis in Children.

BY E. LUTHER STEVENS, M. D.,

Professor of Pediatrics and Clinical Medicine in the Drake University Medical College.
Des Moines, Iowa.

To the practitioner it is a well known fact that the average pulmonary patient does not present himself for treatment in the early stages of the disease. In Iowa alone there are two thousand deaths every year from tuberculosis. On an average each one of these patients infects four persons, some fatally. At the present time there are eight thousand persons in Iowa who have the disease. Believing that a campaign of education on this subject would be most effective if directed toward the school children of the State and through them reach their families, I have prepared a little booklet of information which has been distributed to five hundred and forty-two thousand pupils by the Department of Education and the various county superintendents. By instructing the children regarding the cause of this disease, conditions which make the individual liable to infection, and by teaching them the early symptoms, so that the disease may be recognized in its early stages, there can be a tremendous saving of life.

Thinking it might be suggestive to the profession in other States, the writer desires to call attention to this method of reaching the greatest number of persons in the community in the hope that equally good results may be obtained.

Among the subjects taken up in my instructions to the school children are: Cause—

2. Who are liable to the disease.

3. Can tuberculosis be cured?

4. The chief conditions necessary for successful treatment.

5. Sanitarium needed.

6. Symptoms of disease that should lead to securing careful examination by physician, etc.

The chief point to impress upon the minds of the laity is necessity of destroying the sputum of a consumptive person. Thus, if his sputum is disinfected or burned he will not communicate the disease to anyone else.

Second in importance is fresh air and sunlight. The germ does not thrive in the open air.

Under heading two, anyone weakened by other diseases, such as grip, pleurisy, pneumonia, typhoid fever and measles, is in just the condition in which the germ of tuberculosis can multiply the fastest, because the bodily health or power to resist the disease is lowered. Anyone who habitually or excessively uses alcohol lessens his power to resist tuberculosis.

Anyone who is constantly overworked or poorly fed, or who lives or sleeps or works in a poorly ventilated room, weakens his resisting power, and easily becomes a subject of tuberculosis.

3. Tuberculosis can be cured if proper treatment is begun early. Even patients in advanced stages, if rightly treated, often partly recover, and are able to work and enjoy life for years. Every patient, no matter how far advanced the disease may be, can be so treated that he will not give the disease to those about him.

4. (*a*) early recognition of the disease. (*b*) Fresh air in the greatest abundance, day and night. (*c*) Plenty of the most nutritious food. (*d*) Absolute rest in bed until fever has ceased. (*e*) Carefully regulated exercise. (*f*) All of the above must be used under close observation of a competent physician who will see to it that everything is done for the individual patient that will increase his power to resist disease. While medicine may relieve some of the symptoms for the time being,

there is no drug that will cure the disease.

5. The treatment of tuberculosis is necessarily expensive, and it takes a long time—from three months to a year, even in early cases—so it is very difficult to successfully treat a case in the home. Many States are providing sanatoria for the treatment of tuberculosis, and Iowa has just made provision for such an institution.

6. A cough that persists for a few weeks and resists the usual remedies. (*b*) A constant tired feeling or "run down" condition. (*c*) Loss of weight and strength not otherwise accounted for. (*d*) Any bleeding from the throat or lungs. (*e*) The occurrence of frequent colds.

605 Citizens' National Bank Building.

[Written for the MEDICAL BRIEF.]

Bathing and Feeding in Typhoid Fever.

BY V. L. TREYNOR, M. D.,

Professor of Clinical Medicine in the University of Nebraska, Omaha, Neb.
Council Bluffs, Iowa.

While the modern text-book clearly outlines the treatment of typhoid fever, success in treatment can only follow a most rigid attention to the minor details; the peculiarities of the patient must be taken into consideration, and the plan of treatment modified to meet the indications in the particular case.

If I were asked to name the cardinal features in the management of typhoid fever, I would say (1) proper feeding; (2) the prevention of excessive waste incident to high temperature, by the use of water externally and internally; (3) elimination, through the skin, kidneys and intestinal tract, by supplying the patient with an abundance of water and keeping the body clean and comfortable.

By the judicious use of cold, externally applied, the temperature may be kept down to 103° F., and even in those cases marked by an excessively high temperature it is possible to keep it below 104° F. In my practice I favor the cold pack, for several reasons. It is less likely to produce shock in the sensitive patient and eliminates the bad effects that are sometimes produced in the intestinal tract by the sudden application of cold. The sudden application of cold to the abdomen stimulates peristalsis, and peristalsis, unduly stimulated, may cause a perforation and sloughing of the already ulcerated and weakened intestinal walls.

The application is begun by wrapping the patient in a sheet which has been wrung out of water at the temperature of the body, and applying the cold externally at intervals.

Under ordinary conditions I order the application of cold water when the temperature reaches 103° F., or at the end of the second or beginning of the third week, when the temperature approaches its highest point. It seems wise in some cases not to hold the temperature too low, as the constant bathing necessary to secure this end exhausts the patient, and the beneficent effect of the cold application is consequently negative.

With the exhibition of water applied locally, I make it an invariable rule to insist that the patient drink frequently and freely of water, thereby aiding elimination through the intervention of the skin and kidneys, keeping the general tone of the patient at the highest standard, and the temperature is held more readily in check. In fact, I regard the internal use of an abundance of water of so much importance that I always instruct the nurse to record the quantity of water given, just as assiduously as she does the medicine and food.

At times it is advisable to use a cold enema, using water at a temperature of about 90° F., exercising care that the water is not forced into the bowel under too high pressure. This can be avoided by instructing the nurse to have the irrigator placed not more than two feet above the level of the patient. Many times the temperature can be lowered very decidedly in this manner when other means fail, and additional benefit accrues both from the absorption of the water and the lavage of the lower intestinal tract.

The proper feeding of the typhoid patient is a matter of the greatest importance, and the physician who follows an inflexible plan is due to have many mis-

haps with his patients. Milk, of course, is the sheet anchor, but great abuses occur in its use. I like to have my patients receive an average of about one quart of milk in twenty-four hours, divided, preferably, into eight feedings. The nurse is always instructed to watch the dejecta, and if curds appear the quantity of milk is reduced. It is a very good plan to alternate the milk with egg albumen, which can be given slightly salted, or with a few drops of orange juice added, or in the form of an egg lemonade. Under extreme conditions of irritability of the gastric intestinal tract, it is sometimes advisable to peptonize the milk, but my preference is for the plain milk where the patient can digest and assimilate it. Many of the prepared foods have been greatly exploited in the field of typhoid fever, but the bodily strength of the average patient can be well maintained, and the excessive waste of tissue prevented, by the use of the foods described, varying them according to indications. In fact, it is doubtful whether a patient can be nourished on any of the various liquid food preparations unless supplemented by the use of milk, egg albumen, beef juice, etc., while most of them contain a very decided percentage of alcohol, which may be, and very frequently is, contraindicated.

[Written for the MEDICAL BRIEF.]

Repair of the Pelvic Floor or Colpoperi Neorrhaphy and the Structures Involved.

BY BYRON ROBINSON, B. S., M. D.,
Chicago, Ill.

[This monograph is dedicated to Dr. Howard A. Kelly, in recognition of his meritorious and valuable contributions to medical science.]

Modern American surgery is rapidly becoming merely a technical art. The philosophy of surgery is lost in methods. The diagnosis, the rock and base of medical and surgical therapeutics, is sought *in vivo*, or subsequent to the completion of the surgical procedure. Physicians seek new surgical routes of technique regardless of the anatomic or physiologic bases, immediate or remote.

Professors of gynecology will announce that if a woman does not require a surgical intervention on her genital tract, that she belongs in the domain of the general practitioner. Nothing can be more ridiculous or absurd than such irrational views. Does the oculist, laryngologist, aurist or neurologist send a patient to a general practitioner, forsooth, because he finds no chance for surgical intervention? The gynecologist is a specialist, and should be in possession of knowledge to treat properly any disease of the tractus genitalis, or adjacent visceral tracts which influence it. Gynecology is not merely surgical technique; it includes the knowledge requisite to treat skillfully all diseases of the genital tract. Unfortunately, during the past decade in America there has been a prevalent tendency to exploit a new surgical technique which we will designate as visceropexy; that is, the fixation of mobile abdominal organs. In general visceropexy is irrational. In the gynecological field pexyism is fortunately mainly limited to hysteropexy. This signifies that the pexyite, regardless of the fact that the uterus is a pelvic organ anatomically and physiologically, forces the uterus to assume an abdominal position by means of fixation sutures.

The pexyite appears, in the maelstrom of his dominating surgical technique, to have forgotten the fact that the support of the uterus is chiefly the pelvic floor, and that the uterus is in its normal position—not when fixed by threads.

When perfectly mobile—A healthy uterus is mobile like a healthy testicle. Exudation or suture fixes the uterus just as inconveniently as epididymitis fixes the testicle. Visceropexy rests on an irrational base. It is unphysiologic. It attempts to substitute one pathologic condition (fixation) for another (mobility).

THE PELVIC FLOOR.

The gynecologist must cultivate the ability to build, to form a pelvic floor—the natural support of the uterus, the solid ground of nature on which it rests. Anatomically the pelvic floor is practically the levator ani with its proximal and distal fasciæ. Physiologically the pelvic floor consists of two segments—pubic

and sacral, which, like two bank doors swinging to and fro—to accomplish their function.

The pelvic floor (or diaphragm) consists of (*a*) muscles, (*b*) fascia, (*c*) peritoneum, and (*d*) organs with vessels and nerves. It is attached to the dorso-ventral and lateral walls of the pelvis, chiefly at the margin of its irregular exit. It has three objects, viz.: (*a*) to support viscera and resist intra-abdominal pressure, (*b*) to assist parturition, and (*c*) to aid the rectum and bladder to functionate. The pelvic floor has three apertures or slits—urethral, vaginal and rectal—which pierce it obliquely, similar to the cord in the inguinal canal, the biliary duct in the duodenum, or the ureter in the bladder wall. The oblique slits in the pelvic floor act like valves, which open to functionate, after which they are closed by intra-abdominal pressure and sphincter muscles. A detailed examination of the structure of the pelvic floor furnishes a base for the understanding of its function.

The physiologic pelvic floor appears unbroken when the urethral, vaginal and rectal slits are closed by the apposition of their valve-like walls. The pelvic floor may be divided into the pubic and sacral segments by the oblique vagina—*i. e.*, it consists of two widely superimposed or over-lapping valves.

The pubic segment consists of (*a*) the retro-pubic connective tissue; (*b*) the bladder, urethra, peritoneum, and (*c*) the ventral vaginal wall. The segment is attached or anchored to the distal border of the symphysis pubis in such a manner that it possesses extensive mobility. It exercises its movements chiefly on the elastic retro-pubic connective tissue as a bed. The urethra meets the bladder at right angles, and the peritoneum extends from the bladder to the ventral abdominal wall, enclosing the retro-pubic connective tissue.

The extensive mobility of the pubic segment is due to its limited anchorage to the distal border of the symphysis pubis, but also to the capacity of the peritoneum to become displaced or dissected from the ventral abdominal wall and bladder during motion or distention of the bladder and uterus.

The characteristic of the pubic segment is loose tissue, loose attachments, and free mobility, all of which accommodate dilatation and contraction of uterus and bladder and peritoneum. The dorsal bladder wall is loosely connected to the ventral vaginal wall. The urethra is blended with the distal ventral vaginal wall. The peritoneum over the bladder is loosely attached. The pubic segment is displaced from adjacent loose connective tissue. It will prolapse distalward, whence it is sacro-pubic hernia. The movable pubic segment includes chiefly the bladder, vagina, and, to a certain degree, the uterus, oviducts and ovaries move with it. The pubic segment presents a peritoneal side (three inches), a vaginal side (two inches), and pubic side (two inches).

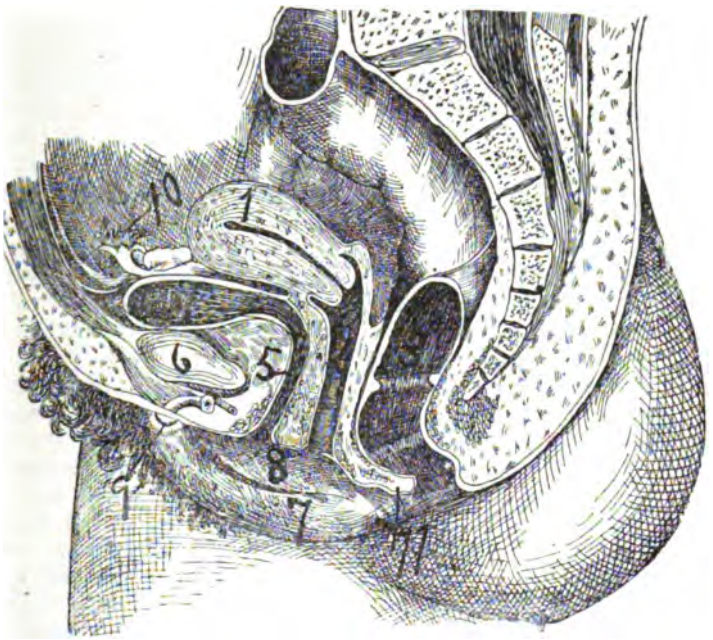
The sacral segment of the pelvic floor consists of (*a*) dorsal vaginal wall, (*b*) perineal body, and (*c*) rectum. It is firmly attached to the sacrum and coccyx by tendinous and muscular fibres. It is a fixed, immovable segment. The only method by which it may be displaced is by the bending proximalward or distalward of the coccyx. The dorsal vaginal wall is loosely connected to the ventral rectal wall as far as the apex of the perineal body. The sacral segment does not prolapse distalward. It may straighten, extend, and become lacerated at its distal end, *i. e.*, in the perineal body. The rectum does not prolapse (in rectocele), its wall distends from lack of fascial support. The peritoneum over the sacral segment is quite fixed. The fixed sacral segment supports the mobile pubic segment. The perineal body is the commercial border of this segment over which the imports and exports of the vagina pass, and is consequently liable to be damaged.

If one views the pelvic floor from its proximal side the first layer is the peritoneum, the second is the subserosum, which proximally is a loose, spongy bed of areolar tissue, which gradually grades into the levator ani fascia proximal, coccygeal, pyriformis and sacral fascia.

The third layer consists of muscles, the levator and the coccygeus and pyriformis. The fourth layer consists of the levator ani fascia distal. Practically the pelvic floor is the levator ani muscle,

with the levator ani fascia proximal and distal. The loose connective tissue serves as an excellent bed in which the pelvic organs functionate. The bladder and rectum dilate and contract in their elastic beds without trauma or loss of integrity.

In parturition, which is the maximum function of the pelvic floor, the uterus utilizes all the connective tissue beds for protection to avoid trauma, and to aid in returning to normal. In labor the contraction of the ventral muscular walls of the uterus draw the pubic segment proximalward, and the child's head drives the sacral segment distalward, and thus the with the three slits—vagina, urethra and rectum, closed, the pelvic floor is represented as intact—unbroken. The vaginal canal is a natural dividing line between the pubic and sacral segments. It is a line of a cleavage between the pubic and sacral segments. It allows the two segments to functionate separately. The ventral vaginal wall bounds the dorsal side of the pubic segments. The dorsal vaginal wall bounds the ventral surface of the sacral segment. In labor the pelvic floor is opened, *i. e.*, the pubic segment is elevated (proximalward), and the sacral segment is depressed (distalward).



LATERAL VIEW OF GENITAL ORGANS.

FIG. 1. An illustration of one of the normal positions of the uterus. 1, uterus; 2, vagina; 3, rectum; 4, bladder; 5, urethra; 6, symphysis pubis; 7, labia; 8, nympha; 9, clitoris; 10, oviductal pavilion; 11, perineal body. In the planning of the illustration a suggestion of Hoffman was employed. The normal uterus is perfectly mobile like the testicle, hence, if the uterus were fixed in the illustrated position it would be dislocated—fixed.

oblique valve in the pelvic floor, the vagina, is opened in parturition, as one passes between two swinging doors by pulling one backward and pushing the other forward. Parturition results in dilatation of the vagina, in straightening or expanding the sacral segment, and in relaxing the pubic segment.

The pelvic floor may be viewed as closed when the vagina represents an oblique slit, the closed rectum and urethra lie parallel to it and to the pelvic brim

In disease the pelvic floor may become displaced by deficient sacral support, *i. e.*, the perineal body may be lacerated and the distal part of the sacral segment straightened or extended. The pubic segment may lose its tone, and intra-abdominal pressure may be so changed that it will drive viscera distalward, *i. e.*, through the vaginal valve. This is excellently demonstrated in retro-position when the abdominal pressure is applied to the uterine fundus, and the cervix, act-

ing like a wedge, opens the segments of the pelvic floor. Uterine prolapse should be termed sacro-pubic hernia.

All herniæ possess a sac, a ring and a viscus. In sacro-pubic hernia the sac is the peritoneum, the viscus is the uterus, and the ring is the loop of the levator ani muscle sheathed in its fascia. The uterus itself has no more to do with sacro-pubic hernia (prolapse), than a segment of the enteron in inguinal hernia. This may be observed in patients with sacro-pubic hernia by asking the subject to "press as at stool," when the ventral vaginal wall appears first in view, next the cervix, and lastly the dorsal vaginal wall, enclosing the fundus.

Bimanual gynecologic examination, which means palpation of the internal genitals, consists in determining the position, consistence, mobility, dimension and conditions of the genitals. This method is accomplished by reason of relaxed psoas and abdominal muscles, mobility of the pubic segment and through shortening the sacral segment by forcing its distal end proximalward. The thighs are flexed on the abdomen to relax the two psoæ muscles. The index finger is introduced into the vagina, while the hand on the abdomen, through the mobility of the pubic segment, forces the genitals into the field of "touch," or palpation. The capacity of elevation of the distal part of the sacral segment explains why the traction forceps brings into view and direct palpation the uterus. The valvular action of the segments of the pelvic floor explains why vaginal hernia seldom follows vaginal hysterectomy.

To extirpate the uterus per vaginam, the pelvic segments or valves are opened, the uterus drawn through, after which intra-abdominal pressure closes them. Vaginal hysterectomy resembles parturition, labor, in delivering the passenger through the vaginal valve. Successful operations for support on the pelvic floor demonstrate that the sacral segment must support the pubic segment, and the pointed cervix must be directed from the vaginal exit or blunted by amputation. The vagina is a physiologic and anatomic line of cleavage between the pelvic segments, while the line between the rectum and vagina is a pathologic one.

For the suggestions of the division of the pelvic floor into pubic and sacral segments I am indebted to the excellent labors of Dr. D. Berry Hart.

Pelvic floor projection is the distance the floor projects distal to a straight line extending from the tip of the coccyx to the distal border of the sub-pubic ligament. Pelvic floor projection averages about one inch.

Intra-abdominal pressure is an important factor as regards the pelvic organs. Intra-abdominal pressure is muscular tension plus atmospheric pressure. It displaces that part of the pelvic floor ventral to the rectal wall, causing sacro-pubic hernia.

The line of cleavage of the pelvic floor as regards sacro-pubic hernia lies between the rectal and vaginal wall. The author has seen hernia of the abdominal viscera which had as a ring the space between the dorsal vaginal wall and the ventral rectal wall. There is no vacuum in the abdominal cavity, the viscera fill it. The tendency to a vacuum is obviated by atmospheric pressure on the abdominal walls and muscular tension.

The effect of intra-abdominal pressure is to force the pubic segment distalward against the sacral; it closes the valve (the vagina) made by the segments of the pelvic floor, and the vagina assumes the shape of a mucous slit. The pelvic floor bears the weight of the viscera, and hence it will project more than the other portions of the abdominal wall. In the same manner the water in a suspended rubber bag will, by its weight, project its lower part beyond the rest. In genu-pectoral position, by drawing the hymen toward the rectum, air rushes in, distending the vagina and forcing the pubic segment proximalward with the viscera.

The practical utility of the intra-abdominal pressure becomes apparent in the consideration of the uterine position. In the erect attitude the uterus is in physiologic anteflexion and the intra-abdominal pressure acts chiefly on its dorsal surface. This prevents sacro-pubic hernia, if the sacro-uterine ligaments are normal. Should the utero-sacral ligaments elongate, the cervix passes distalward, the uterine body passes dorsalward and intra-abdominal pressure acts on the fundus

and ventral uterine surface, inducing the uterus to descend or prolapse (sacro-pubic hernia).

Elongation of the utero-sacral ligaments and retroversion are the beginning of sacro-pubic hernia, uterine prolapse. The reason fat subjects have more hernia than spare ones, is because an excessive quantity of fat becomes deposited within the abdominal cavity, increasing the intra-abdominal pressure and weakening the abdominal wall. Intra-abdominal pressure forces distalward the pelvic floor ventral to the ventral rectal wall. Intra-abdominal pressure acting on healthy viscera only makes them more secure against sacro-pubic or inguinal hernia, because the hernial openings, especially the vaginal and inguinal canals, are valve-like or oblique. Relaxed pelvic exit represents laceration, elongation and separation of the levator ani fascia superior and inferior. Successful colpoperineorrhaphy means the repairing of the levator ani fascia proximal and distal.

CONTRAST OF PELVIC SEGMENT (PHYSIOLOGIC PELVIC FLOOR).

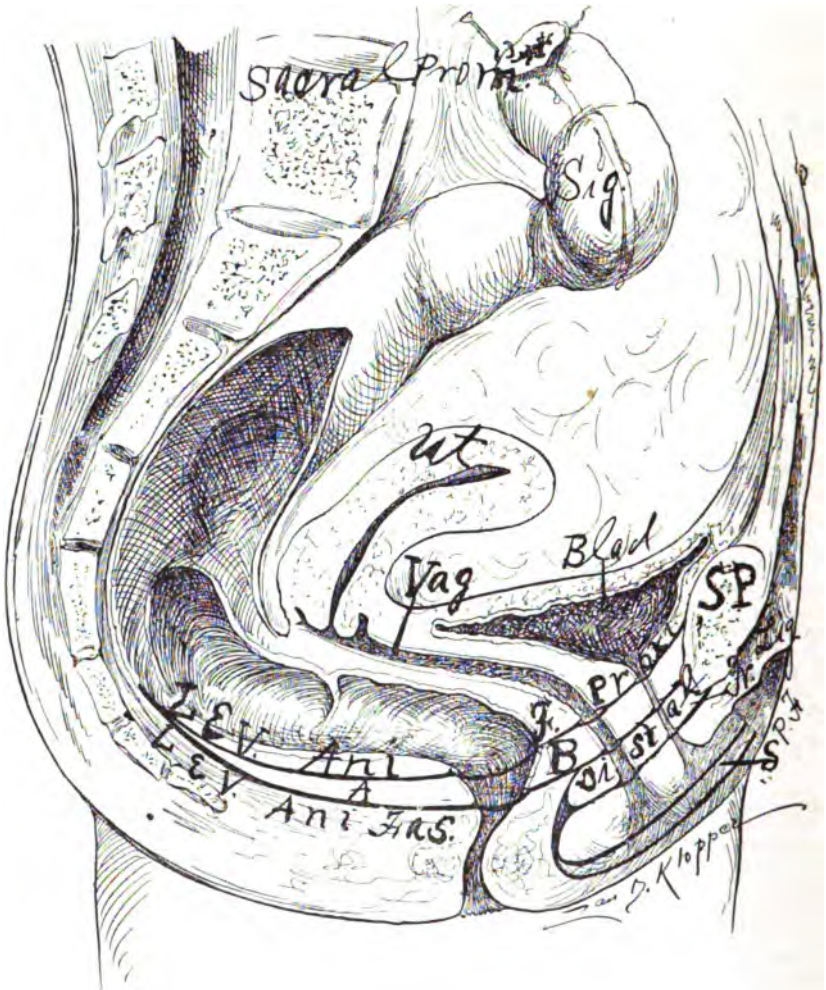
PUBIC SEGMENT.	SACRAL SEGMENT.
(1) It is visceral.	(1) It is vertebral.
(2) It is movable.	(2) It is fixed.
(3) It is composed of loose tissue.	(3) It is composed of firm tissue.
(4) In labor it is elevated.	(4) In labor it is depressed.
(5) It prolapses.	(5) It does not prolapse, but straightens, and the perineum becomes lacerated.
(6) It is composed of bladder, retropubic tissue, bladder peritoneum and anterior vaginal wall.	(6) It is composed of posterior vaginal wall, perineal body and rectum.
(7) It is the proximal ventral valve of the pelvic floor.	(7) It is the distal dorsal valve of the pelvic floor.
(8) It is loosely attached to the pubis.	(8) It is firmly attached to the sacrum and coccyx.
(9) Its peritoneum is movable.	(9) Its peritoneum is fixed.
(10) It is entirely displaceable.	(10) It is entirely non-displaceable.
(11) Rests on sacral.	(11) It supports pubic.
(12) It is elevated in genu-pectoral position by admission of air.	(12) In genu-pectoral position it is undisturbed or depressed.
(13) It is triangular.	(13) It is quadrilateral.

The pelvic fascia I have partially renamed. Fascia should be named according to the muscle or structure with which it is most intimately associated. The fascia of the pelvis, quite an independent structure, begins exactly at the ilio-pectineal line, or the brim of the pelvis. It lines the whole pelvis, being perforated by three apertures, viz.: Rectum, vagina and urethra. The obturator fascia is divided into proximal and distal by the white line (arcus tendineus), which is a remnant of the ventral connective tissue ligaments of the bladder. The white line extends from the dorsal surface of the pubis to the ischial spine, the white line not only divides the obturator fascia into proximal and distal, but serves as the origin of the levator ani muscle.

The obturator fascia proximal begins at the ilio-pectineal line, and extending to the white line, partially covers the obturator internus muscle. The obturator fascia proximal is in relation with the obturator nerve and vessels. The obturator fascia distal, extending from the white line to the ischial tuberosity, partially lines the obturator internus muscle. It is in relation with Alcock's canal. which transmits the pudic vessels and nerves. The ischio-rectal mass of fat in the perineal region extending from the white line to the median raphe, and extending from the white line to the ischial tuberosity, is surrounded by fascia that enclose the muscles which functionate or control the anus, vagina and urethra. Fascia supports and muscles functionate the viscera. The fascia applied to the proximal surface of the levator ani muscle is the levator ani fascia proximal.

The fascia applied at the levator ani muscle on its distal surface is the levator ani fascia distal. The levator and fascia proximal and distal terminate in the median raphe, or by blending with the pelvic viscera. The levator ani muscle is peculiarly strengthened by its double fascial sheath proximal and distal. The fascia covering the coccygeal muscle is the coccygeal fascia. The fascia covering the pyriformis muscle is the pyriformis fascia. The fascia lining the ventral surface of the sacrum is the sacral fascia. We thus have different names to the fascia of the pelvis which are in relation with definite structures. On the levator ani fascia proximal and distal depends the integrity of the pelvic floor. The levator ani muscle does not sustain the pelvic viscera. It

is performed by its fascia. The fascia of the pelvic thus consists of (*a*) obturator fascia proximal, (*b*) obturator fascia distal, (*c*) levator ani fascia proximal, (*d*) levator ani fascia distal, (*e*) pyriformis fascia, (*f*) coccygeal fascia, (*g*) sacral sages for nerves and vessels which are surrounded by lymphatic sheaths which serve to carry infection from one space to another. An ischio-rectal or perineal abscess could influence inflammatory processes in the pelvis and *vice versa*,



PELVIC FLOOR SEGMENTS.

FIG. 2. A diagram of the pelvic floor segments. (a) Pubic (ventral vaginal wall, bladder and retro-pubic fat); (b) sacral (dorsal vaginal wall, perineal, body and rectum). Also it represents the fascia of the pelvic floor (especially the levator ani fascia proximal and distal) in mesial section, demonstrating that the levator ani is reinforced by strong and dense sheets of powerful fibrous membrane. In this illustration a suggestion from Hart and Dickinson is employed. The pelvic floor anatomically consists of the levator ani muscle with its proximal and distal fascia. Physiologically it consists of the pubic and sacral segments, two superimposed or widely overlapping valves. A. B, levator ani muscle; Lev. Ani F. Prox, levator ani proximal; Lev. Ani Fas. Distal, presents a powerful sheet of fibrous membrane lying on the distal surface of the levator ani; S. P., symphysis pubis; Tr. Lig., triangular ligament.

fascia. There are other macroscopical apertures in the pelvic fascia than the vagina, rectum and urethra, through which the pelvic and perineal regions are connected. The pelvic and perineal regions are directly associated by pas- through apertures which, as nerves or vessels, are sheathed by lymph channels. The pelvic fasciæ are strong, fibrous membranes which sustain the pelvic viscera and form essentially the pelvic floor, and they maintain in definite anatomic and

physiologic relations the muscles, apertures, nerves, blood and lymph vessels. In pelvic lacerations following labor, it is lesions of the pelvic fasciæ that causes distress and damage. An operation which relieves suffering and repairs the lesion must be the one which restores the pelvic fasciæ.

The patient with rectocele, vesicocele, or sacro-pubic hernia has sustained lacerations of the pelvic fasciæ, especially the levator ani fascia, distal and proximal. Restoration of the pelvic fasciæ restores visceral support. Repairing of the pelvic fascia aids in restoring the levator ani muscles to its original relations.

(To be Continued.)

Ottomar Rosenbach, M. D., Berlin.

On March 20th died, in his fifty-seventh year, Professor Ottomar Rosenbach. The cause of his death was mediastinal tumor and corresponding heart affections. For a long time he had been a great sufferer. Having always been a hard worker, his main complaint to me in his letters was always that he could not work as he was accustomed to. By Rosenbach's death THE MEDICAL BRIEF has lost one of its sincerest and valued friends. He always spoke of the BRIEF as the fearless, independent medical journal which, like himself, stood up for uniform aims in medicine and for independence of the clinic in opposition to the prevailing fashion and methods of specialists, combating the domineering autocracy of those bacteriologists whose methods of treatment are based exclusively on researches in the laboratory. There can be no difference of opinion, even among those who do not agree with him in some points; all will agree that among the prominent men of our profession and our time, Rosenbach was, more than any other, an original thinker, observer and investigator, who made no concessions to the extravagant fashions in medicine of the present day. He was a profound linguist and favored reform of onomatology. Several papers of his were written for THE MEDICAL BRIEF. His biography and portrait appeared in the April issue, 1904. A. ROSE, M. D.

[Written for the MEDICAL BRIEF.]

Influenza and Relapsing Fever.

BY JOSEPH D. HARRIGAN, M. D.,
New York City.

A comparison of the symptoms of influenza with those of the epidemic disease known as relapsing fever, brings to light some very remarkable analogies.

In influenza, according to Zuelzer:

Invasion.—"The *onset* of the disease is generally sudden, as the name 'lightning catarrh' indicates. As a rule it is marked by a decided chill, or by malaise, lasting several hours, with slight chills alternating with heat. Only in rare cases are we apt to have malaise for several days, and an established cold beforehand."

In relapsing fever, according to Flint:

"Abruptness of invasion characterizes the disease. The attack is sudden. There is no prodromic period. The seizure is almost always marked by a well-pronounced chill, which is immediately followed by febrile movement. Usually the patient at once takes to the bed; but, in some cases, one, two or three days pass before there is this evidence of yielding to the disease."

In relapsing fever, according to Lebert:

"Characteristic, however, in these exceptional cases, with prodromes, is the quick onset of the disease itself."

Fever.—In influenza, according to Zuelzer:

"In the severer cases the fever, even at the beginning, seems to attain a rather noticeable intensity. * * * According to the older views, it is remittent or subcontinuous, and its course is lighter in the day, but in the evening and at night marked by increase of the various symptoms, and a rise in the frequency of the pulse and an increased heat of the skin. Under certain circumstances the temperature occasionally rises transiently as high as in pneumonia or continued fever."

In relapsing fever, according to Flint:

"The fever attains quickly to either considerable or great intensity, as denoted by the pulse and axillary temperature. Thus, of two cases in which the disease was developed in Bellevue Hospital, in one, the pulse, on the first day, was one hundred and twenty and the temperature 103° F.; in the other case the pulse

was one hundred and thirty and the temperature 103° F."

In relapsing fever, according to Lebert:

"Soon after the onset the morning temperature exceeds 102.2° F., reaching in the evening 104° F., and in a few days the remittent fever shows, morning and evening, a temperature one or two degrees higher; that is, from 105.8° to 107.6° F."

Pulse.—In influenza, according to Zuelzer:

"The pulse exhibits a varying character; it may be full and moderately accelerated (ninety to one hundred), but is also described as small and weak. It was not infrequently found irregular, or very changeable, so that, as Graves observed, it was often completely changed in from six to eight hours."

In relapsing fever, according to Flint:

"During the continuance of the first paroxysm the pulse and temperature generally denote a persistent intensity of fever, the pulse ranging, in different cases, from one hundred to one hundred and forty."

In relapsing fever, according to Lebert:

"The pulse becomes accelerated to one hundred and eight and one hundred and twelve in the morning, and one hundred and twenty and more in the evening. It is weak, though with tolerable fullness and tension; frequently quick; sometimes dicrotic."

Mucous Membranes.—(I) Respiratory.

As far as the respiratory mucous membranes are concerned, not so very striking an analogy is evidenced in relapsing fever, as compared with influenza, as exists between the latter disease and other of the great constitutional epidemic diseases. But an analogy between them exists nevertheless.

Thus, in influenza, according to Zuelzer:

"The symptoms are essentially of a catarrhal nature. We find most frequently marked cold in the head, with considerable discharge from the head, and sometimes epistaxis; redness of the conjunctiva, with abundant lachrymation; catarrh of the mucous membrane of the throat, larynx and bronchi; also sore throat; difficulty of swallowing, hoarseness, tendency to cough, and a burning or tickling sensation in the throat. The mucous membrane of the cavities of the nose, mouth and pharynx is generally found reddened and the tonsils swollen. * * * Auscultation frequently reveals sonorous, or, in places, crepitant râles; still there also occur cases in which all the auscultatory phenomena are very insignificant, or absolutely wanting. Yet many patients show more or less important evidence of dyspnea. According to Graves' view, they often occur with intermittent or rhythmically returning remissions. In many cases they are probably the consequence of complications, but sometimes no demonstrable lesions can be found in the lungs."

Here, as usual, the inevitable and obfuscating word, "complications," of which I have spoken so often, in other articles, is intruded, and if not taken for what it is worth would completely confuse us in interpreting the significance of symptoms and lead us far astray from the essentials of the great epidemic *constitutional* diseases.

"Influenza dyspnea" is, I think, the most proper and scientific term to apply to this development in the great *constitutional* disturbance present in this affection. It is not to be regarded as a "complication," but is part of the process, as likewise are many of the other disturbances, hitherto, in my opinion erroneously, spoken of as "complications."

Graves assumes a disturbance in the function of the vagus to explain such cases; Biermer is satisfied that they depend upon congestions of the lungs, which furnish few indications to auscultation or percussion, unless edema occurs.

With many patients these phenomena go on to great oppression, marked dyspnea, pain in the precordia, etc.

Pleuritic stitches, too, and pains under the sternum are observed without any appreciable physical changes. In certain epidemics these suffocative states are rather frequent.

In relapsing fever, according to Flint:

"Among the complications of relapsing fever * * * the most frequent are pneumonia (both lobular and lobar) hemorrhagic infarctions of the lungs, pulmonary edema, edema glottidis, pseudomembraneous laryngitis and pharyngitis, pleuritis. * * * Only a small number

of patients are affected with any of the complications which have been mentioned."

As opposed to this non-prevalence of these complications (so-called), we have the observations of Lebert:

"Mild bronchitis is *not infrequent* in relapsing fever, and usually remains insignificant. * * *

"While in former epidemics in Breslau pneumonia was very seldom observed, yet in that of last winter (1873), we noticed it quite frequently, as, indeed, had been previously the case elsewhere." * * *

And again he states:

"The respiratory organs present no peculiarities when complications do not exist, but certainly during the last Breslau epidemic (1873), *many patients perished of pneumonia.* This pneumonia, which might be either single or double, presented the usual appearances of diffuse inflammation of the lungs, the remaining parts of which were also edematous."

Now, proceeding to that form of relapsing fever, called bilious typhoid, which, on account of its severity and mortality, has given excuse to some observers to be regarded as a distinct disease, but not, it is pleasing to remark, so considered by all. We find the same inevitable re-duplication of influenzic symptoms, which it has been my privilege to mention in other writings, apparently forms the basic groundwork of all epidemic disease.

We find, according to Griesinger, quoted by Lebert, in Ziemsen's cyclopædia:

"Closer examination shows numerous quickly appearing localizations; often bronchitis or pharyngitis * * * hoarseness, difficulty of swallowing, with croupous deposit on the mucous membrane of the pharynx, bronchitis, extensive lobar pneumonia." * * *

As far as the pathological anatomy in this disease is concerned, Lebert says:

"Petechiæ and ecchymoses are found at quite an early period, as well externally as internally, upon the mucous and serous membranes. The organs are generally deficient in blood, and diphtheritic exudations often exist upon the mucous membrane of the pharynx, extending even into the larynx, and sometimes assuming an ulcerous character. Enlargement of the bronchial glands, bronchial catarrh, lobular centers of collapse, or more considerable infiltration of the lung are observed."

Mucous Membranes—(II) Gastric and intestinal:

In influenza, according to Lebert:

"The mucous membrane of the digestive organs is likewise affected in many cases, although generally not to so high a degree. Loss of appetite, increased thirst, a coated tongue, a bad, pasty taste; sensitiveness of the epigastrium, and, not infrequently, colicky pains and diarrhea, or nausea and vomiting, accompany the disease. In other cases there is persistent constipation."

Turning to relapsing fever, we find, according to Lebert:

"The fever, intense and continued from the commencement, is accompanied by thirst and loss of appetite, less frequently beginning with nausea and vomiting. The patient complains of a bad taste, the tongue is thickly coated, and later dry. The bowels are somewhat constipated, or there is a slight intestinal catarrh, which is more frequent and persistent than the vomiting, which sometimes appears at the same time."

The dyspnea, previously mentioned, in influenza, has its counterpart in relapsing fever.

Lebert says: "With the decrease of the fever * * * the breathing, previously hurried and *somewhat* difficult, becomes regular."

Running briefly through various other symptoms of influenza, we find them easily paralleled in relapsing fever.

Nervous Symptoms.—In influenza Zuelzer says:

"The prostration of the strength is very marked from the beginning. * * * They complain of severe headache. * * * We find, together with considerable depression, very severe pains in the limbs. At times they are limited to particular muscles, tendons or ligaments, or are perceived as a generally diffused hyperesthesia over the whole body. Patients complain particularly often of hard dragging or boring pains in the calves, the hollow of the knee, the shinbone, or the back."

In relapsing fever, according to Flint:

"A symptom referable to the nervous and the muscular system is highly characteristic of the disease under consideration. I refer to arthritic and muscular pains, more especially the latter. * * * Pains in the loins, the calves of the legs, and the muscles in other situations, are generally much complained of."

In relapsing fever, according to Lebert:

"The muscles of the body, however, are the seat of severe pain * * * it is situated in the muscles of the neck, back, chest and abdomen, and in the upper and lower extremities. It is most severe in the latter, particularly in the calves. The character of the pain is splitting, piercing, boring, or more indescribable."

"In many cases, particularly among females, a general hyperesthesia of the skin shows itself during the attack."

Sweating.—In influenza, according to Zuelzer:

"Sometimes frequent sweats show themselves."

In relapsing fever, according to Flint:

"The perspiration in some cases is abundant."

And according to Lebert:

"Sweats occur."

Relapses.—In influenza, according to Zuelzer:

"Relapses are not rarely observed, and sometimes occur even in the course of the same epidemic."

Eyes.—"The influenza process," according to Zuelzer, "is followed by various sequelæ, and these are so frequent that many observers have indicated them as immediately connected with the essence of the disease. * * * Among them may be counted such cases as present an intense catarrh of the conjunctiva or of the ear."

In relapsing fever, Flint says:

"In some epidemics affections of the eye have been observed from one to four weeks after the termination of the disease."

Now, this comparison of symptoms might be continued through the whole gamut in the diseases under consideration, in similar manner as was done by the writer in paralleling the symptoms of influenza and typhus fever, as likewise those of influenza and cholera, but it seems to me unnecessary to lengthen out the subject further.

I think that a sufficient analogy has been shown to exist between nine-tenths of the symptoms as to prove that there is a common foundation upon which these diseases are constructed, and, as in relapsing fever, there are the added developments of a swollen spleen and a swollen liver, it would necessarily follow that the construction of this disease was based upon influenza as the foundation, and not, of course, influenza upon relapsing fever.

As regards these extra developments in the latter disease, it must be remembered that the law in physics, known as the parallelogram of forces, is equally applicable to the human body and the chemical and electro-chemical processes transpiring therein as it is to any other entity in the physical world.

In conformity with this law, the energy developed as a consequence of the poisonous chemical material absorbed by the system, finds expression in what might be called points of least resistance, in this particular case, the liver and spleen.

Combined with this law in its application to the human body we must take into consideration also the natural selective action of various chemical agents involved in the general constitutional disturbance.

This selective quality in the disease-producing or disturbance-producing chemicals absorbed finds its counterpart and its analogues in the selective action of chemicals used by us in medicine to combat disease, as, for example, calomel, ergot, quinine, digitalis, etc., each of these having a distinctive sphere of action.

In conclusion, it seems as reasonable to consider, in view of the fact that nine-tenths of the symptoms of influenza can be shown to exist in other of the epidemic diseases, then the factors that go to make up the result—influenza—must also go to make up the result: relapsing fever, or typhus fever, or cholera, as the case might be.

It seems to me an absolutely simple proposition that one disease can be contained in another; just as simple, in fact, as the proposition in arithmetic, one number can contain the prime factors that also go to make up another. The prime factors

of eight, for example, being two, two, two, the bringing into the question of another factor does not eliminate the eight, but simply increases its value, so that we find the result of the prime factors two, two, two, two, to be eight, doubled, or sixteen.

Thus it seems to me easy enough to explain the similarity of the vast majority of the symptoms in the varying phases of epidemic disease, by assuming certain factors (chemical and electro-chemical) to form the groundwork, as in influenza, the superstructure being constructed upon this foundation, the variations in this superstructure being due entirely to the varying chemical and electro-chemical factors of environments, localities, seasons, etc.

In fact, the whole process is like a grand and complex laboratory experiment, in nowise differing, except in grandness and extent, from the simple experiments that yield ozone instead of oxygen, hydrogen peroxide instead of plain water, and so on almost *ad infinitum*.

[Written for the MEDICAL BRIEF.]

Rectal Diseases — the Bete Noire of the Physician.

BY HOWELL B. GWIN, M. D.,
Nashville, Tenn.

In a series of articles I desire to give some of the salient teachings of twenty years' experience in the treatment of rectal diseases, endeavoring to avoid as far as possible technical language, I will seek to be scientifically exact in the use of such phraseology as will be readily understood by all. If I shall put any brother physician to thinking along new lines, and if I shall present any helpful suggestions, this effort to do good will be rewarded.

Let us consider:

I.

HEMORRHOIDS OR PILES.

The word hemorrhoid comes from two Greek words, meaning "flowing blood," a name which does not define, but is probably given on account of one symptom, bleeding, which sometimes appears. Piles is from a Latin word, meaning "a ball," and though plural in form, is sometimes used in the singular. An accepted definition of a hemorrhoid is "it is a vascular tumor of the mucous membrane of the rectum, the anus, or both." Piles may be classified into two varieties: External and internal. It is easy, however, to mistake concerning external piles, which do not bleed, and may be due to flaps of the skin which have hypertrophied. It is true that these flaps or folds may be inflamed, producing pain and discomfort. In external piles the skin alone is involved, and the tumor is outside the external sphincter muscle, and can not be pushed back into the bowel. In old cases internal piles protrude outside the anus, but may be pushed back into the bowel to remain for a greater or less period of time. In examining a patient it is always well to learn whether there is a combination-pile, that is, one partly external and partly internal, and also to understand well the nature and occasion of the protrusion. The appearance of the rugæ and the condition of the mucous membrane of the parts, whether healthy or unhealthy, and, of course, a minute examination of the protrusion itself, are necessary. I have found that the primary lesion is due to the separation of the mucous and muscular membranes, and have reasoned that the circulation must be restored, absorption accomplished, and the re-attachment of the membranes secured before there can be a permanent cure.

In reaching a diagnosis of any disease no competent physician relies entirely upon the testimony of the patient. This, of course, will supply certain data, but his diagnosis to be authoritative and conclusive, must embrace all the facts connected with the disease. Just here let me warn my younger brethren never to sacrifice facts to theories, and never to cling to remedies based on conditional theories and limited facts. The true physician, while accepting known facts as regards diseases and its treatment, diligently searches for facts yet unknown and essential. To the care of such a physician the progress of medicine is committed.

In rectal diseases the physician must be thoroughly acquainted with the gen-

eral constitution, and with every abnormal feature which may or may not be directly or indirectly connected with the case in hand. He must never be satisfied with a mere digital examination, but with an up-to-date rectal speculum examine and treat each and every lesion in the anal strait. Of course, his patient will tell him of a sense of fullness and heat, a tight sphincter, throbbing pain, tendency to strain, sometimes attended with itching sensation, and a slight elevation of temperature and more or less discomfort in any position he may assume.

We must be careful to differentiate hemorrhoids from polypi, malignant or cancerous growth, villous tumors, prolapsus, pruritusani and hemorrhages (of some of these we will speak in a subsequent article).

It is doubtless true the human race has always been victimized by piles. Moses, the oldest authentic writer, tells us of an epidemic of "emerods" sent as a punishment upon the people. Many years later the author of the first book of Samuel records a similar calamity. No generation, nor sex, nor class of men, nor climate is free from this disabling malady. Let us, therefore, consider for a moment the etiology of this disease. Many veins in the rectum form the hemorrhoidal plexus. A part of this blood is returned by the internal iliac to the inferior cava, the rest through the inferior mesenteric to the liver—these veins have no valves. It has been held that the principal cause of this disease is due to the obstructed passage of the blood through little slits in the muscular wall. A further explanation is that piles spring from diseased coats of the blood vessels, terminating in and under the mucous membrane. It is also true that some pressure from above, interfering with the venous circulation, produces piles. Other general causes are morbid growth of the spleen, liver, uterus, ovaries and prostate, which give rise to venous obstruction. Other diseases, such as catarrh, stone in the bladder, urethral obstruction, etc., give rise to hemorrhoids. A proximate cause is the pressure of hard and stagnated feces upon the rectal ampullæ or sigmoid flexure. In short, the causes of hemorrhoids are, (1) the weakening of the forces that move the venous blood from the rectum to the heart; (2) obstruction of the venous outflow from the rectum , and (3) predisposition. Young blood vessels germinate from the older vessel walls and form a cavernous tissue—the result is piles.

Treatment. It is not my present purpose to enter into the details of the treatment now enjoined and practiced by our professional authorities. This has been fixed in two kinds: Palliative and operative. The palliative embraces ointments, salves, anodyne solutions, hot poultices, acid applications, suppositories, etc. The operative includes the cautery, ligature, scissors, knife.

In concluding this article I desire to ask a few questions: What is the percentage of cures by these treatments? Brother physician, have you been satisfied by their use? and have your patients been satisfied? Did the disease return again? In what length of time and in what proportion? Is it wise to stubbornly stick to a course that does not give us adequate results? Is it possible to secure a better mode of treatment? Are you thinking and searching for a remedy? No answers to these questions are asked for. We simply urge you to *think.*

(To be continued.)

[Written for the MEDICAL BRIEF.]

Collinsonia or Stone Root.

BY E. E. TRUITT, M. D.,
Maquon, Ill.

In reply to Dr. I. Moore, of Kingsland, Texas, in regard to the therapeutics of stone root, March number of BRIEF, would say, as a specialist in catarrhal diseases, that we have used the fl. ext. of collinsonia with marked success in catarrh of the larynx, bladder, and, in fact, in catarrhal troubles anywhere in the system, but its specific effects seems to be on the larynx, and we would more recommend it in coughs having their origin in the larynx, in aphonia and weakness of the vocal cords. Next to this, we would prescribe it alone, or in combination with fl. ext. of buchu in catarrh and irritation of the bladder, with the addition of bicarbonate of soda. I hope this may be of benefit to the Doctor.

[Written for the MEDICAL BRIEF.]

Humbug.

BY S. E. GIBBS, M. D.,
New York City.

A devout disciple of Mrs. Mary Baker G. Eddy asked me the other day if there is not a good deal of humbug about the practice of medicine. To which, of course, I indignantly replied: "Certainly not."

But his question set me to thinking whether it could be possible that such a thing as humbug could, in any way, be associated with our noble profession.

When a Christian Scientist asks such a question it would seem as if the time had arrived to review the situation and so be prepared with an answer should such a question againg be propounded. And, to date our investigation as far back as possible, it would seem proper to begin with the newly fledged M. D. who, after purchasing his horse and carriage on the installment plan, drives through the crowded streets at a two-thirty pace, visiting-list in hand, which he diligently peruses, and in which is inscribed the name of his one long-looked-for patient, while his corrugated brow reveals the intense anxiety to get through his arduous labors in time to hear the inspiring tones of the supper bell. And next morning robs all the young ladies on the block of their "beauty slumber" by the clatter of his horse's hoofs as he starts on his urgent call to — Riverside Drive or Central Park.

Humbug, do you say? No, the young man is merely a victim of insomnia, complicated with excess of vitality.

Then there is the doctor you meet, and to whom you, in the innocence of your heart, and with all the frankness of youth, impart the doleful information that practice is dull, and who proceeds to cheer you and raise your spirits by informing you that this is a sort of "off day" with him, and then counts on the fingers of both hands the calls he has made (and he would need his toes also for the calls he has to make in the afternoon), and you feel depressed, but, rightly or wrongly, find it difficult to suppress the murmur beneath your breath—humbug! Wrong again. He has recently erupted his wisdom teeth, that is all.

Also the "professor" (perhaps of chemistry only) called by his friends to meet you in consultation in a critical case of pneumonia or typhoid fever, and who, posing before your patient as a specialist, criticizes your treatment, and carries away in his pocket all the financial resources of the family. Humbug? No; he has a large family and a small salary.

The doctor who writes the glowing testimonial to the virtues of a proprietary concoction, and who prefaces his article with the stereotyped statement that "He is averse to recommending any proprietary medicine, but in this case is compelled by his love for humanity to break through his rule," and so he writes what may be termed his virgin testimonial; of course, completely unbiased by the fact that he is the owner of sundry shares of stock in the manufacturing company, but which fact he omits to mention, may be perfectly honest—but?

Suppose we now come a little nearer home, and call attention to that pile of reprints on the reception-room table, bearing your name in large type on the title page for the inspection of your patients. Why does the supply never diminish? And does your printer charge by the thousand or by the month?

The many diplomas, certificates and society emblems on the walls look pretty, and are, no doubt, noticed by patients who will be duly impressed with your importance, so better let them remain where they are. That pile of bank notes on your desk, however, though they may indicate your financial prosperity and corresponding successful practice, would, perhaps, be safer in your cash-box or pocket, provided they are genuine.

Why allow your poor horse to stand at your door for half an hour in cold, wintry weather while you carefully pack your instruments in a satchel? That old chronic rheumatic patient you are to visit today will not need them, though he may be interested in listening to your casual remarks about the rare operation you are to perform this afternoon. But it's hard on the horse.

Why, when purchasing the above-mentioned animal did you exhibit a decided preference for a piebald, rather than a sorrel, gray or bay?

Don't you know that piebald horses are considered less robust than those of another color?

Why place that large six foot by four glass case on your office wall, and fill it with obsolete surgical instruments. It's a deal of trouble to keep them clean and bright, and you can carry all the instruments you are ever likely to use (outside of a hospital) in a very small handbag.

Those foreign labels on your trunk when you return from your annual "week off," are impressive, cheap, and can be purchased at various places downtown, and are silent witnesses of your sojourn in the hospitals of Europe; it being well-known that only frivolous society people and insurance company officials visit European capitals for mere pleasure. Physicians go there for "experience in the hospitals." The necessary knowledge of a foreign language, in order to understand French or German professors, is easily acquired, but, strange to say, is as easily forgotten on returning to one's native soil. In fact, I have known some physicians to inadvertently leave it behind them on the ship. To successfully pose as a specialist in any case to which you may be called on your "return from abroad," is a valuable accomplishment, and will enable you to demand and receive a much larger fee than the all-round general practitioner is usually able to command. It will, perhaps, be noticed that although the original purpose of this article was to ascertain whether there are any humbugs in medicine it will be found to contain also some hints that may prove of value to the recent graduate, especially if he be from a rural district, and aspires to a city practice. Along this line we might suggest that he keep a good supply of medical journals (not omitting the BRIEF) in his reception-room, thereby imparting an air of erudition to that apartment. The doctor himself may never have read any of them (excepting, of course, the BRIEF), but the fact of his having subscribed for them is evidence to his patients that he is no humbug, but is thoroughly "up to date."

That long list of calls to patients in the most fashionable section of the city, and which completely covers the upper side of the slate in the hall, need not prevent the messenger from the more humble patient inscribing his name and address thereon, he can turn the slate over, and if it remains over all day, you may lose nothing, and by reversing it next morning, will save considerable valuable time that might be wasted in rewriting it.

When a prospective mother calls to engage you to attend her in her confinement, it is quite permissible to place her on your obstetric list as number one thousand five hundred (audibly, of course); she will then have great confidence in your skill and experience, and in her eagerness to secure the services of so eminent an obstetrician, will, no doubt, fail to take note of the date of your diploma on the wall. Besides, women love to be humbugged almost as much as men do.

When using the stethoscope do not be tempted to omit to count audibly the number of râles, mucus, submucous, crepitant and subcrepitant, and other adventitious sounds that may be absent. It is perfectly right to impress the patient with your skill as a diagnostician, and if he is not sick, he will think he is; which, so far as your bank account is concerned, is in effect identical.

The humbug in the above procedure is not easily detected, and has, therefore, sometimes been successfully practiced by the specialist.

Those little unmedicated tablets which you, dear reader, so carefully dispense with minute directions as to their administration when you are doubtful about your diagnosis, and require a little time to read up. Do those little tablets not contain, in addition to sugar of milk, at least a fraction of a grain of extractum humbugii?

And, oh, my esteemed homeopathic brother (whisper to me the answer), why does the liquid in each glass, a dose of which is to be so faithfully administered every hour alternately, often differ so little in taste but so much in color?

That imposing electrical machine which is always out of order when your patient is, and working well after he has recovered, cost a lot of money, but to use the words of the good old deacon who once advised me to occupy a front pew in church, "it pays."

And now may I be permitted to ask the celebrated surgeon who so disinterestedly advised that hysterically inclined patient to furnish the necessary material for his afternoon clinic by submitting to an operation for appendicitis, thereby enabling him to complete his series of one hundred consecutive cases without a death. (See reprint on office table).

Did you really open the abdomen? And are you quite sure that you did not forget to thread your needle, notwithstanding the mute but conclusive evidence of that neat row of stitch-holes on either side of the wound?

And then we have the "medical expert" who, while waiting for the ink on his diploma to dry, poses as an "alienist," notwithstanding the fact that he is possessed of only a rudimentary knowledge of the anatomy of the nervous system, and none whatever of psychology, and by his testimony on the witness stand humiliates the entire profession, lowers it in the estimation of the public and makes of it a laughing stock. Is such a man a humbug, or is he only afflicted with cranial hypertrophy?

On the other hand, we see two groups of so-called experts, learned men, thoroughly versed in all that pertains to the functions of the brain and nervous system, with all its vagaries and deviations from health, opposing each other, one group being paid large fees by the prosecution, the other by the defendant, and flatly contradicting each other, and we are led to ask: Of what value is such testimony? And do all the gentlemen engaged give their honest opinion, or are some of them suffering from anemia of the bank account?

I leave the answer to the reader.

On impartially reviewing the situation I am forced to admit that there may, perhaps, be just a little humbug connected with the practice of medicine, but only a little.

22 East 126th Street.

Inclosed find P. O. money order for one dollar, for which send me the BRIEF. It is one among the best journals that comes to my office. I want it as long as I practice medicine.—W. M. SOLOMON, M. D., Krupp, Ark.

[Written for the MEDICAL BRIEF.]

Homeopathy vs. Allopathy—Comparative Materia Medica and Therapeutics.

BY N. SISCA, M. D.,
Killarney, Queensland, Australia.

(Continued from page 300.)

XI.

The following few cases, published by homeopathic physicians, whose names are a guarantee of absolute trustworthiness, will, I think, better than anything else, give a fair idea of the difference between homeopathic and allopathic therapeutics:

Case 1.—Mrs. T. had become very low in consequence of childbirth, attended with violent puerperal fever, the cure of which had required several months. She now complains of a very painful pressure in the region of the left lobe of the liver. She looks ill, though not icterical; her tongue is coated; she is ill-humored; of anxious mood. This is attended with vertigo, which has the peculiarity that she feels better when up, while the vertigo returns when she lies down. This is the more strange, since the patient is enemic, and the vertigo of enemic patients usually passes away while lying down.

Repeated and most careful examination gave no positive result, except a little more painfulness about the spot, which would probably correspond to the gall bladder and its environs, radiating therefrom into the cardiac region or into the pit of the stomach.

Lycopodium, *China* (cinchona) and *avena* gave no relief, and it occurred to me that if I succeeded in improving the general state of her constitution the other ailments would be relieved. I turned, therefore, my attention to *calcarea carbonica*, which was given, and which speedily cured the pressure on the liver and the vertigo.

The clew to the selection of calcarea was that among its symptoms we find: Abdomen distended, thick and hard, *pressive pain in the liver*, also, *sensation of attacks of vertigo.*

What should be the allopathic treatment of a case like that? It is quite possible that small doses of sod. salicyl., together with a short course of Blaud's pills, might

have done as much good as the calcarea, but the fact remains that calcarea given on homeopathic lines cured, and cured quickly.

Calcarea carbonica, or *calcarea ostrearum*, are the homeopathic names for our *calcii carbonas*. The name, *calcarea ostrearum*, is accounted for by the fact that the homeopaths, instead of using the purely mineral salt in the form of powdered chalk, use the soft white substance, which is found between the external and internal layers of the oyster shell.

Allopathy has practically no use for carbonate of lime. We find in text-books that it is antacid and astringent, and that it should be given in doses of ten to sixty grains, but it is pretty safe to say that nobody ever prescribes it. Homeopathy, on the contrary, ranks it among the most valuable remedies in its *materia medica*, and never gives it in doses stronger than the 1/1000 of a grain.

Case 2.—Ovarian congestive neuralgia. On September, 1895, a young woman, aged twenty-six; fresh complexion; medium height and stoutness, with fair hair and gray eyes, came to me conplaining of pain in the side, the situation of which she indicated by placing her hand over the left ovarian region; also of pain in the back—lumbar region. She has had a slight pain in the left side for years, but latterly it has become worse.

"When I breathe it seems to draw up, and then it pains me. I don't feel it at my periods, nor for a little while after—a few days; sometimes a week. It is a kind of stabbing pain; it is always there a little, but when I draw my breath it stabs worse." Sometimes she fancies there is a little swelling, but it goes again, and she cannot say that it makes any difference to the pain. No pain during urination, and no increased desire to evacuate the bladder. Suffers from constipation; going two and three days without a stool. Pain in rectum at times; generally when the pain in the side is worse. Menstruated at seventeen; always regular, except on the month before last, which she missed, while away from home. On returning home the period came on again. Prescribed podoph, 1x. t. d. s.

October 7.—"I feel much better; have not had the pain for more than a week. Bowels also better. No pain in the back since beginning to take the medicine."

Patient continued well for a period of between two and three years, when she had a slight return of the ovarian pain, which was again removed by *podoph*.

In the pathogenesis of podophyllum there are these symptoms: Pain in right ovary and uterus; numb, aching pain in region of left ovary.

How would such a case as that be treated by an allopath? Like other neuralgias, on general principles. A good few years ago *conia* pessaries were said to be a good remedy for ovarian neuralgia, but we do not hear much about it now. *Gelsemium* "is said to be useful," but on the whole, the allopathic treatment of ovarian neuralgia rests on the general principles of hygienic measures, plenty of rest, iodine painting and tonics.

Case 3.—J. M., forty-nine, tailor, has been suffering for the last twelve months from the effects of overwork and worry. First seen on September 30, 1901. He complains of being dreadfully low and depressed; can not sit down to his work; has to rush out of the house if he attempts it. Says that if he lies down during the day he has uncontrollable thoughts of suicide. Suffers much from insomnia; wakes in the early morning about two or three o'clock, and can not sleep again, and feels very badly then. Has obscure nervous sensations and pains in the head. Pulse small and feeble. Prescribed *aurum muriaticum* (chloride of gold), 2x four times a day, with hot beef tea at bedtime, and some light nourishment on awakening in the early morning.

October 8.—Feels better; less depressed, and is beginning to sleep better.

October 18.—Going on well.

October 25.—Looking very much better, and sleeping well now; spirits greatly improved.

After this his attendance became less regular, but at the last visit he said he had resumed his occupation as a tailor for the first time for over a year.

What would we do in such a case as that? The patient said he had had plenty of tonics without being any the better for them. What else could we think of? We have no remedy for mental depression and low-spiritedness. True, we always have

the bromides with us, but in a case of this kind they would probably make depression worst depressed, and, therefore, the only thing we could think of would be plenty of rest and a change of air.

Case 4.—Psoriasis in a parrot cured by arsenic.

A beautiful parrot of the Channana variety was caught about a year ago. It was apparently in full health. Its feathers were bright green, with red streaks on the middle of the upper surface of the wings. It was put in a cage. After about a couple of months' confinement it was noticed that feathers were dropping off, first from the breast, then from the wings and from the tail. Most of the downy feathers of the breast became white before dropping off. In the course of three or four months the bird had lost so much of the feathers of the wings and of the tail that it was unable to fly; so, during the day it was let out of the cage, and allowed to walk about, and after nightfall was put in its cage again. Notwithstanding this freedom given to it, the disease did not show any sign of improvement. The ladies from time to time gave the bird baths of turmeric water, which, according to them, is a powerful insecticide, but these baths were of no use. In the course of ten months from the commencement, the bird lost nearly three-fourths of its feathery covering. Singularly enough it did not lose its appetite. It could eat well, and, in fact, it was rather greedy.

Then I thought of trying some medicine, and arsenic was the first medicine that came to my mind. I could not, however, make the poor thing take the drug. I put some globules of a high dilution of it in its milk, but seeing that I had put something in the milk it would not take it. At last I thought of mixing with the grain soaked in water with which we used to feed it a drop of the medicine, and he ate the grain. In about four or five days the dropping of feathers ceased. In about a week the downy feathers of the breast, which had become white, began to turn green. In a fortnight feathers appeared in the wings and the tail, and began to enlarge to their natural dimensions. In the course of a month the bird had nearly regained its full and beautiful plumage.

How would we treat a similar case?

Since both homeopathy and allopathy recommend arsenic as one of the remedies for psoriasis, the only ground of difference in a case like this would be the dose. Leaving the allopathic dosage to the discretion of the reader, I will just say that in the case quoted above the quantity of arsenic given was a single dose of one drop of the 30x (thirtieth decimal dilution). Translated into plain figures this represents the nonillionth of a grain of arsenic. Shall we say *ne quid nimis?* The homeopaths would reply that it cured the parrot.

[Written for the MEDICAL BRIEF.]

Practical Notes.

BY DR. A. ROSE,
New York City.

II.

Many years ago a physician in a fashionable German watering place reported in some medical journal an original observation which proved to be of more importance than the discovery of a new bacillus. Unfortunately, I have forgotten the name of the author, and the name of the journal—as it will happen when we do not at once write down such names in our scrapbook. The most remarkable fact is that I never saw any mention of the discovery in all literature, and, notwithstanding my speaking of it repeatedly in medical societies in my lectures, nobody seems to pay attention. Now I will bring it before the readers of THE MEDICAL BRIEF, because I know that there are many who will listen to practical and valuable new and original observations, even if they are not in the line of bacteriology, the prevailing topic of the present time.

The physician of whose discovery I wish to speak was a gynecologist. In his spa he attended many cases in which there was complaint of backache, and in which this backache had been attributed to some uterine trouble. On examining many patients with this complaint he became finally convinced that there existed a number of cases in which there was absolutely no pathological condition of the generative organs recognizable. The characteristics in such instances were: There was distinctly marked pain on pressure over one of the processes of a vertebra, from

the first lumbar vertebra down to the fifth. The pain—without being produced by pressure—was felt during the night when the patient was in bed, and more especially on awakening in the morning. As a rule, no pain was experienced during the day. These patients had a slight elevation of temperature in the evening; were thirsty at that time, and had all the feeling of being not well; of being under a constant strain. Many of these sufferers had been under gynecologists' care. The uterus or the adnexa were accused of being the cause of all the ailment; curettage and other heroic measures had been resorted to, without avail. In one of my own cases the patient had been treated by a specialist in rectal surgery; he had accused the coccyx, and removed this bone, which was quite innocent, in fact, in this case, and the result was that the patient was the worse for the operation. Judging from my own experience, I think that many women are treated for all sorts of gynecological diseases who suffer from nothing else but the described affection of a process of a lumbar vertebra.

Now, what is this affection? It is periostitis, periostitis confined to a vertebral process which will never heal of its own accord, but which will be cured by anti-periostitic treatment. All cases which came under my observation had been of years' standing, and since I read the paper mentioned, and since my attention has been directed to this kind of ailment, I have seen a great many, and had the satisfaction of seeing each and every one recover in the course of time.

Now, what is the treatment? First apply two leeches to the very spot at which there is the characteristic pain on pressure; use a glass provided for the application of leeches, in order that they may really attack this very spot; have them applied at night, so that the patient is not inconvenienced by having to be in bed during the day while the leeches are attached, and while the oozing of blood goes on after they have fallen off. The next day, and every day following, for weeks and months, according to circumstances, have the spot and the nearest surroundings painted once daily with tincture of iodine. In case this tincture causes soreness of the skin, discontinue the application for a day or two, *i. e.*, until the skin is intact again. Internally, give iodide of potassium or sodium, ten grains in water, three times a day, and if, unfortunately, the patient is subject to iodism and the different admixtures to prevent iodism do not prove satisfactory—and as far as I know none of them are reliable in all cases—do not experiment with them, but give the following pills:

℞ Lithii Iodati 1.50.....22½ grains.
Pulv. et Ext. Quassiæ.....q. s.

M. Et fiant pil. No. Viginti 20. Sig.: One pill morning and night; after some time three pills a day may be administered.

Iodide of lithium is very hygroscopic, and for this reason a good deal of solid mass has to be used in making these pills. They have to be kept in a well-closed bottle.

I have never seen iodism following the use of these pills.

Patients will at once, after the application of these leeches, feel free from pain, and this will be pronounced by them with great satisfaction after they have been annoyed with the pain for years. Under the anti-periostitic treatment by iodide of potassium or iodine, or, if these and other forms are not tolerated, by iodide of lithium, they will be well; perfectly cured, after a shorter or longer period of time, but we have to call their attention to the fact that, perhaps, the treatment may have to be continued faithfully for months.

These cases will give satisfaction in an exceptional way. Patients may have consulted many physicians, celebrated gynecologists, may have had heroic measures applied, and now they are relieved and cured by simple and most rational means.

My experience is that one can not induce the high-up specialist in gynecology, or any other specialty, to take notice of anything that is so simple and rational that it appeals to every-day common sense, as long as it is not in accordance with their own profoundly learned teachings, or as long as such a simple, rational affair has been overlooked by them because it could not be found anywhere in the elegant text-books.

But now I come to ask a great favor of the readers of THE MEDICAL BRIEF which is to give me a little divertisement and satisfaction.

Write your prescription for iodide of lithium as I have written it, and underline *flant* pillulæ, and ask your druggist what he says to it. He will, as it happened in my own experience, bring the large volume and show you *flat*=make, and if he does so, let me know, and I will furnish conclusive evidence that we have not to write *flat* pillula, but *flant* pillulæ. I should like to see the photograph of the man who wrote in the great book of pharmacopœia flat=make, and thus led all who do not know Latin into the absurdity to write flat pillulæ. We shall have a gaudium at the expense of the flat=make men.

[Written for the MEDICAL BRIEF.]

Acute Pulmonary Edema.

BY EDWARD C. ROTHROCK, M. D.,
Palestine, Texas.

In pulmonary edema, prompt, intelligent medical treatment is imperative if fatal results would be avoided. The great danger is in its sudden attack without any warning. The patient may appear quite well, or may complain of being unwell, or may be afflicted with some heart trouble, and a sudden attack of dyspnea is manifested, an untoward symptom that is seen in edematous lungs. Pulmonary edema may occur at any time under existing conditions, and at a time when aid cannot promptly be obtained, and may prove fatal from this cause; frequently the trouble is not recognized until it is too late to render adequate relief. Persons appearing in perfect health are suddenly stricken, caused by valvular insufficiency. The heart weakens under the strain. The kidneys are frequently a factor, interstitial nephritis, uremia existing to some extent, and may occur at any period of Bright's disease, generally in the advanced stages of that trouble. It occurs sometimes in pneumonia and other pulmonary diseases, and I have seen it frequently in malarial diseases. A malarial-pseudo-tubèrculosis, which condition is frequent in malarial countries. The condition presented is terrifying and extremely distressing. The sufferer is propped up in bed, supported by friends, gasping for air, suffocating, restless; trying to get relief by change of position; a profuse cold, clammy perspiration covers the body; a pallor, cadaverous cyanosed appearance is present; lips livid; eyes sunken and turned appealingly for help—for relief that, in some cases, can not be afforded by human aid. The pulse is rapid and weak; bronchial rattling, and moist râles are heard over the chest, showing the edematous condition of the lungs. Incessant hacking, dry cough, is present, with very little expectoration, and what little is expectorated is a whitish froth, which may at times be streaked with blood, but gives no relief. A dilated heart is often found in such cases, with a systolic murmur. Small arterial vessels are highly endowed with contractile and dilating power, and in relation to the capillaries regulate the blood supply to those vessels. This relation has the power of stimulating or sedating the heart's muscle by the existing condition of the arterioles, their contraction and dilatation producing blood tension, or lessen that condition, and is a force in the functions and frequently a factor in alterations that take place in the structures of the heart. By blood pressure, contraction of these vessels, the blood is dammed backward in the arteries. The heart is required to do double work to overcome the greatly increased resistance. This resistance, if continued, leads to hypertrophy of the heart. As sometimes seen in cases of arterial sclerosis, a loss of elasticity and rigidity of the arterial walls. Again the free dilatation of the arterioles sedate and lessens the work of the heart, as resistance is less, and by producing this condition causes rest in a dilated, feeble and exhausted heart. Therefore, the condition of the capillary area is very important; its influence is not only exerted upon the cardiac symptoms and conditions, but upon the other pathological conditions that are existing. Within the heart's structure is contained the power of automatic and rhythmic motion by presence of the cardiac-ganglia, this power, aided by the irritability of the cardiac muscular tissue. This action, rhythmic, is independent, to some extent, of the nervous system, but is controlled by the cerebro-spinal and sympathetic system and fibers from the vagus, originating from the fourth ventricle and upper cervical part of

the spinal cord, and causes inhibitory action. The acceleratory influence is given off principally from the cervical sympathetic fibers communicating with the vasomotor center in the medulla. The inhibitory influence slows and weakens, but conserves the heart's force. The acceleration increases the force rate of contractions of the heart, and may, if continued, exhaust its energy, and end in a complete collapse. Persons "broken down" by excesses are liable, as indulgence in alcoholic drinks, syphilis, chronic malaria, old nephritic cases, etc. Yet, in such conditions, a toxic influence exists, operating on a valvular insufficiency. Our attention should be called, and efforts afforded as soon as possible for prompt relief, and to use the drug or drugs that will relieve this untoward condition, and ward off impending death. Atropine is one of the best drugs for pulmonary edema; its action is exerted on the vagus; its terminal branches of the lungs. Atropine 1/60 to 1/100 grain, hypodermically, is frequently prompt to relieve, and should be used in small doses; repeated as often as necessary. It is a cardiac, respiratory and spinal stimulant to the entire motor center, dilating and increasing the capillary vessels, and equalizing the circulation, lowering blood tension. In large doses atropine has contrary effect; heart rate becomes rapid, arterial tension is raised and circulation rapidly increases by stimulating the sympathetic and paralyzing the cardiac, inhibitory ganglia. Nitro-glycerin is next to atropine, if not as good, used hypodermically, small doses, 1/100 to 1/200 gr. Nitroglycerin will relieve the spasm of the arterioles; is a vascular stimulant, dilating the peripheral vessels, regulating and equalizing the circulation, and lessening blood pressure, and thus prevent internal congestion by paralyizing the sympathet'c system, or vasomotor center, or both. Tumultuous action, spasm of the heart, is overcome by relaxation of its inhibitory apparatus. Hence pulmonary troubles, as cardiac asthma and pulmonary edema, etc., are frequently relieved and cured by the aid of the general circulation. Nitroglycerin and atropine are similar in some of their effects. Manifested in small doses, a cardiac stimulant slows the heart's action, strengthens its pulsations, causing deep respiration, a regular pulse and lower blood pressure by lessening of peripheral resistance. Atropine has a decided selective action over the respiratory centers in the medulla, quickening and causing deep breathing. Atropine could be used alone or alternated with nitroglycerin. In alternative treatment we get the effects of two drugs, which is often useful. Venesection — "bleeding" — has been recommended by some. We have never resorted to it in this disease. There are cases that can not be saved by any treatment, as the condition of the central organ is so debilitated by dilatation, valvular diseases, etc., that the heart will not respond to any stimulant. Remedies should be used hypodermically, as time is precious, and is wasted to give drugs by mouth. The stomach is slow to absorb and appropriate the remedy. Most of it can not be absorbed in the existing condition. By hypodermic, the drug has effect in a few seconds. By stomach, before the drug can act the patient may die. We have been very successful in treating pulmonary edema with atropine and nitroglycerin. If the heart's muscle is characterized by feeble pulse, frequent, irregular, intermittent, insufficient contractions, small and fluttering pulse, then strophanthin, 1/60 to 1/100 grain every ten minutes, hypodermically, until effect, then at longer intervals. Its action is manifested quickly; more so than drugs of its kind. It acts with great energy, and in small doses it is a powerful cardiac stimulant, increasing the force of the ventricular systole, raises blood pressure, and diuresis is produced. It acts through the blood direct on muscular fiber, increasing the contractile power of stripped muscles. Large doses will paralyze the heart in systole. It relieves dyspnea. Strophanthin is a charming remedy in failure of compensation, aortic regurgitation, valvular lesions, due to endocarditis processes and atheromatous changes. Strychnine is also a good drug in small doses, 1/100 to 1/150 grains. A stimulant to the spinal cord, reflex motor, vasomotor and sensory, dilates the pupils; a stimulant to respiration; increases vision; a tonic; aids digestion; increases peristalsis; gives tone, strength to the walls of the intestines. It has an affinity, selective action for nerve matter,

stimulating the multipolar ganglia in anterior columns; therefore, a powerful stimulant to the respiratory, cardiac, muscular and nervous apparatus.

In dyspnea from pulmonary troubles, cardiac failure, strychnin, in small doses, is often prompt to relieve. But even when medical aid is had early in the attack of pulmonary edema, a large per cent will die, for pulmonary edema tends to a fatal issue. Copious effusion of serum into the pulmonary tissues takes place, and not only into the inter-lobular spaces, but into the air cells, so that the patient's lungs are water-soaked, and is literally drowned in his own blood serum. Whisky, or other stimulants have, in nearly all such cases, been administered before the physician's arrival, but has done little or no good. The congested and edematous lungs still labor, and the churning, moist râles still continue over the chest, and suffocation is impending. Remedies can be given by mouth that may do some good, but resort may be had immediately to the hypodermic method of treatment. Prompt action is the motto in this trouble. Atropine is the mainstay; nitroglycerin can be used in alternation. If alcohol, ammonia, ether, or whatever drug is used, it should be used hypodermically, and used every ten or fifteen minutes, or every half-hour, as indicated, until effect is had, then every two or three hours.

The effects of the medicament should be continued indefinitely, or a day or two, if needed, until the safety of the patient is assured. We must not forget that the price of life is prompt and vigorous action in pulmonary edema.

[Written for the MEDICAL BRIEF.]

Sidelights on the Question of Diet.

BY AXEL EMIL GIBSON, M. D.,
Los Angeles, Cal.

The physiological center of exchange in and through which the hunger sensation of the cells are translated into self-consciousness is the medulla oblongata—the extraordinary agent which stands between the cerebral and the spinal, the psychic and the vegetative spheres of organized existence, constituting a self-adjusting relay station or switchboard for the exchange of the ceaseless rush of nerve impulses, arriving from the field of myriad functional operations.

Appetite is the medullic interpretation of hunger into terms of self-conscious appreciation. In other words, hunger is cellular vacui, due to nutritional exhausture, and has its psychic or self-conscious expression in sensations of desire for food—appetite. Hence it may be said that hunger is cellular (physiological) desire, while appetite is cerebral (psychic) desire; and while thus the former always gives rise to the latter—other things being equal—the latter may or may not indicate the presence of the former.

For while hunger springs from cellular needs, manifested in terms of capillary suction, and indicated in the presence of cellular vacui, *i. e.*, the actual need of replenishments for exhausted energy—appetite may be generated through the play of the mind on imaginary needs, thus giving rise to desire, which latter is to psychic, self-conscious nature, what cellular vacuum is to physical nature. But while cellular desire always expresses true needs, that must be filled, psychic desire expresses imaginary needs, that in most cases stand for mere vegetative luxury, and ought not to be heeded.

That psychic hunger, or desire for food, can give rise to the sensation of appetite, even in the absence of true cellular need, is due to the fact that the mind, through the power of imagination, can introduce tempting images of sensation, and thus generate a desire for indulgence, a desire which, while without the physiological basis of cellular desire, nevertheless can manifest in terms of physiological vacuum and suction.

It is this similarity, or, rather, identity of the metabolic and psychic phases of desire, that confounds the medulla oblongata. Induced to respond to the latter phase, she initiates impulses in the taste-cells and associated gustatory secretions, resulting in appetite, while the subsequent reflex impulse per pneumogastric nerve affects a flow of the requisite digestive fluids, without the metabolic phase being involved in the process.

It is under the stress of psychic desire that the human being has developed an appetite far in excess of his powers of di-

gestion and assimilation. From a saving genius, intended to guide the individual in selecting and partaking of the proper quantities and qualities of nourishment, the functions of appetite have arrogated a mind-and-reason-controlling power which, like the ancient dogs of Acteon—Acteon's dogs in the tale proceed to attack and destroy their own master. A slave to his appetite, the individual proceeds with a constantly decreasing power of self-control, to undermine and wreck the foundation of his physical existence. For while the food sent into the stomach, in response to the superinduced "psychic appetite," may succeed in starting adequate gastric secretions and subsequent digestion, it naturally fails to create a corresponding physiological need in the cells of nutrition. Being thus entirely uncalled for, and unwanted, this surplus of nourishment becomes a positive burden to the entire metabolic exchange, taxing the cellular operations to the utmost by necessitating processes of neutralization, isolation and final expulsion of the waste-matter from the system, involving the strain and stress of liver, kidneys, lungs and heart, and the irreparable losses of wasted nervous energy.

As "psychic appetite" is inducible at almost all hours, without regard to regularity or need, and with every gratification followed by the appalling train of functional exhausture, the stomach sooner or later will fall short in secreting the requisite digestive fluids. So far, however, from heeding the warning signal for the need of functional rest and recuperation, the patient, not infrequently acting on medical advice, takes recourse to a "tonic digestant" to whip the stomach into line with the morbid cravings of an insatiable gluttony. But, as in this case, the stimulation is of a wholly chemico-mechanical character, with no appeal to the medulla oblongata; it fails to invoke the aid of the "psychic factor," and hence is inadequate to elicit the secretion of digestive fluids.

A mere chemical irritant, the tonic can arouse no other response in the gastric activity than that of self-defense, resulting in secretions, not, indeed, of digestive juices, but of a defensive fluid intended to protect the epithelial covering and mucous lining of the stomach from the inimical presence of the irritating agent. A meal introduced into the stomach under such auspices will be subject to no other digestion than that due to mechanic friction in an alien non-digestant medium. And furthermore, as the aseptic condition of the ingested food is insured and maintained only through the disinfective properties of the hydrochlorid acid contained in the gastric juice, it at once becomes evident that the absence of normal secretions in a stomach charged with food will precipitate the latter into a state of fermentation, starting processes of decomposition in place of digestion, and cellular intoxication in place of assimilation.

It needs no extraordinary powers of imagination to sketch the picture of cellular and functional wreckage following the train of outrages thus committed against the sanity and sancitity of vital principles. After exhaustive, though futile efforts of the stomach to effect a digestion, the mass of infected food-stuff, reeking with bacteria, moves down the intestinal canal, poisoning in its course the succus intericus of the alimentary canal and associated vital chemistry of the entire metabolic exchange, inflicting incalculable damage to every function in the system. Inadequate to remove from their respective fields of operation the poisonous waste-substance thrown into the circulation, the organs of depuration, liver, kidneys, lungs, suffers a constantly increasing percentage of impurities to remain in the various tissues and viscera, retarding and endangering the execution of every physiological office in the bodily commonwealth, while the functions themselves are advancing toward ultimate breakdown.

The peril of the glutton is heightened by the highly-condensed food in which he indulges. For it is utterly out of the question for an individual, held captive by the modern commodities—the time and muscle-saving devices in home and office—to give rise in his physiological exchanges to wants and necessities that would even approximately justify the intake of such tremendous over-plus of muscle-heat-and-energy-yielding material as found in the quantity and quality of his daily food-consumption. The uric-acid-intoxication

of meat-eating; the hepatic congestion due to the highly condensed and artificially specialized form of nourishment contained in cheese, butter and oils; the physiologically considered, largely incombustible, because of nuclear or germinal character of the egg, which, similar to the whole family of grain and pulses, indicate existence in a stage of generative retirement, where the vital batteries of latent, but highly specialized energy, stand for embryonic nutrition rather than normal, post-embryonic diet. The, both quantitatively and qualitatively, excessive diet of our ancestors, while not by any means conducive of highest physical and mental development, had, nevertheless, the power of maintaining a metabolic balance, because of the bodily activity and extensive out-of-door existence to which they were compelled, by their crude methods of industrial exchange; and to introduce into our highly condensed and elaborate bill-of-fare the quantities of their dietary indulgencies, would result in no less a failure than to attempt to feed a modern wood-stove or compressed-coal-brick-heater with the roots and logs of green wood, which the old folks enjoyed to see burn in their open fire-places. Adjustment of the individual to his environment furnishes the sole guaranty for a continued progressive evolution, and any neglect in living up to this axiom leads inevitably, by the very law of life, to the arrest of life.

There can be no doubt that a great many of our hygienic and sanitary advisers have a large share in the nitrogen- or proteid-madness which lately has taken possession of the public-health movement. The people, especially the physically weak, are charging their digestive and assimilative powers with tremendous overplus of proteids, eggs, meat, butter, cheese, etc.—leading only to added waste, added loss and lessened vitality. And while nature, by constantly aiming at a restoration and support of normal processes, may, for longer or shorter periods, prolong the tragic spectacle of conscious or unconscious self-destruction, the final metabolic break-down is unavoidable, and the juggernaut of Bright's disease, diabetes, pneumonia or consumption, in the course of events will ruthlessly crush out the panting life-breath of the victims of vulgar self-indulgence.

Lately, however, light from authoritative quarters has begun to be shed on the subject. Professor Chittenden's investigation at Yale will prove itself to be a mighty lever toward a breaking down of false ideas in the philosophy of diet.

Beyond the shadow of a doubt this scientist has demonstrated that complete muscular efficiency, metabolic balance and uniform weight can be maintained only by a sweeping reduction of all the nitrogenous substances hitherto regarded as vital necessities for the virile and adequate support of active physical existence.

The theory, moreover, that a diet of fruit and vegetables is insufficient to maintain metabolic equilibrium, has no real basis in physiological chemistry and progressive assimilation. In his experiments along these lines, Voit found that a human subject, sustained during two weeks on an exclusive diet of carbohydrates, fruits and vegetables, was perfectly able to maintain the nitrogenous balance in his system, which proves beyond doubt the fact that fruit and vegetables contain sufficient proteid to meet any exigency arising in the unfoldment of vegetative life. The full power of a fruit and vegetable diet to sustain any phase or strain of physical activity has, perhaps, never been fully ascertained, though a chemical analysis of comparative food-values in fruit and vegetables published recently in *Journal Jardin d'Acclimation* (Paris), furnishes the statement that persimmons are found to contain no less than sixteen per cent nitrogen in the sum total of its substance. Bananas, pomegranates and cherries show twelve per cent; pears, eleven; apples, ten; grapes, nine; melons, cranberries, pineapples, eight per cent, and so on; which means that fruit alone has resources of nourishment which, independently of any other form of nourishment, can amply sustain and keep in perfect balance the assets and liabilities in the economics of human physiology.

Nor do we lack facts of practical demonstration bearing directly upon this subject. For not long ago a London lawyer, who is also a well known and quite successful novelist, published a personal

statement in the *London Lancet* concerning his diet, which, for no less than three years, had consisted entirely of apples—baked, stewed or raw. His only beverage was juice obtained from strained apple-pulp. He enjoys perfect health and vigor, experiencing a tireless endurance, as well in his professional as literary labors. In fact, he found his mind brighter than ever, and felt an increased power to successfully undertake great things. His experiments in exclusive fruit diet has certainly, so far, been a perfect success.

But the experience of the London lawyer is neither unique nor miraculous. Cases of similar character begin to meet us everywhere, and have a basis in perfectly normal physiological powers. In a recent copy of the *Vienna Tagelelatt*, that chanced to come under my observation, a description was found of a hermit in the Hungarian woods, who, for some months, under constantly increasing vigor of his mental and physical faculties, sustained himself on a diet of fresh grass.

Such departures from the ordinarily accepted code of diet merely go to indicate the presence of unsuspected resources of life-sustaining powers contained in the simplest forms and manifestations of universal nature. I heard once a chemist declare as his sincere conviction, based on personal observation, that the force latent in a glass of water, if atomically liberated, would suffice to move every wheel of industry in the City of Pittsburg. The secret and subject-matter of diet is not found in the quantitative, but in the qualitative; not in digestion, but in assimilation; not in an unreasoning abandon to the play of mere sensory impulses, but in the aim and object of reducing sensory and functional excitement into purposive life-promoting ends, and to translate the over-plus of saved vital energy into available storage batteries for future needs. The aim, perceived or not, of evolution, is toward simplicity of form and complexity of expression; the transmutation of quantity into quality; the systematic saving of labor, and the accentuation of its result, not merely in the sphere of physical industry, but in the sphere of mental and moral exaltation; in the sphere of dynamic balance between body and soul. For every momentum of energy, physical or mental, expended on the development of bodily powers, if not actuated by motives of universal, self-eliminating usefulness, means a growth of the body at the expense of the soul; means the inversion and living denial of the profound statement given to us by the sage of Nazareth, that "the life is more than meat, as the body is more than raiment." And it is along this line of individual evolution that humanity has gone astray, and lost its grip on the real issue of life, by becoming absorbed in the unessential and unreal. In identifying himself with his body, man has lost his consciousness of being a soul. His vital interests, in the course of his matterward departure, have become centered on the mediate and temporary; on the peripheral excitation and ephemeral thrills of sensory exhilaration. Passions, desires, appetites, etc.; in fact, every motion, good or bad, has its genesis and development in mental processes and attitudes. As the exercise of a physical organ responds in added growth, so a mental faculty, or corresponding desire, doubles and redoubles its strength by the very attention paid to it. In its larger cosmic process the essence of life holds suspended in itself as latent force, every impulse or emotion; every possibility of self-concious expression; and it devolves on the individual himself—on his attitude and receptivity to vital issues—if the formation of the composite streams of thought, feelings and emotions shall contribute to the rise or fall, the construction or destruction of manhood, will-power and character.

For every movement of the mind connects its owner with a principle or characteristic, corresponding to the subject-matter of the involved feelings. Thus, if permitting his mind to linger on the scenes and pleasures connected with eating, or any other purely animal functioning, anticipating and reveling in imagination over sensuous delights arising from the gratification of the morbidly swelling-appetites, the latter will grow and absorb all higher and purer impulses, such as self-restraint, moral will, altruism etc., until finally, when arriving at the coveted event, the individual will find himself swept off his moral basis, utterly inadequate to sustain his moral dignity and

self-respect in dealing with the temptations put in his way.

A desire is a conducting wire, by which the individual connects himself with batteries, generative of forces and emotions similar in character to those that agitate his own mind. To entertain a thought of envy, hatred, gloom, passion, desire, longing, etc., means thus to invite these powers to enter the council-chamber of the mind, and to subject his judgment and reason to their influence. The process is not imaginary; it induces the play of scientifically determinable forces and energies. Its formula is expressed in the simple statement that a mental attitude or self-conscious desire lays the mind open to the invasion of that very force by which the desire is characterized, while the ensuing action expresses the resistless burst of the mental energies already accumulated and fashioned in the mind during the preceding contemplation; the translation, so to speak, of idioms and symbols into the concretely and vitally applicable text of current comprehension. Hence to wrestle with emotions, arising from already generated force-centers is futile; our only safeguard lies in mental autonomy—the positive refusal of the mind to entertain any desire or emotion other than those in conformity with conscience and moral law. Regrets, self-chastisements, grief, remorse, etc., are all negative processes, whose modus operandi are to connect the prostrate mind with the object and source of its distress, and hence serve no other purpose than to widen and deepen old channels for further invasions of the devitalizing forces. Only one successful remedy is available; the mind off from the coveted subject! Sever the connection; tear down the wires of desire which place the mind within the disastrous reach of the alien force and imperils its safety. Personal desire is the wooden horse which the defenders of ancient Troy permitted to enter their besieged city, not suspecting that its gigantic limbs and trunks were packed with armed enemies.

The only successful campaign with an uncontrollable appetite, promising any success, must proceed in tactics similar to those by which Wellington once conquered Napoleon; the tactics of what may be called progressive retreat. Fight with an alleged stronger foe is fatal. An army once defeated, and with no reinforcements of any kind, will certainly continue to be defeated as long as the given conditions prevail. There are two ways, however, infallible and sure, ever open to the soldier of the passion-swept battle-field of the mind: to avoid engagement by positively excluding from the mind any thought or emotion connected with the foe, and a reenforcement of defense by establishing connection with the resistless forces of light and truth. And the philosophy of the process is not difficult to grasp. Any kind of fear or worry, no matter what the character of the motive back of it, is inevitably detrimental to development and strength. Moreover, as fear and worry are always concerned with self-interest, it follows that at the bottom of these devitalizing emotions is to be found a selfish motive, which ever leads to the isolation of an individual from sources of regenerative life. And from this it again must follow that a mind which deals with personal existence merely for the pleasures and gratifications it yields—its successes and failures; its hopes and fears, etc., while refusing to accept the larger life, the life of inter-social, inter-human progress as part of its vital equation—must result in a closure of the circuit for which it has been a vehicle, and the subsequent lapse of the body and soul into a state of lawlessness, confusion and dissolving friction, where moral force and determination of will is speedily degenerating into abject submission to the will-o'-the-wisp of every assailing temptation. For protracted selfishness must inevitably lead to a dissolution of the moral will with the subsequent break-down of our mental and physical nature.

A tremendous advance toward the attainment of will-power and self-control is found in the realization of the value of example as a fashioner of inter-social life —example not only in terms of physical action, but also as mental states. In the sphere of mind is no air-tight compartments, and no efforts, good or bad, in thought or action engendered by an individual, can fail to impart a corresponding effort on the life and destiny of the rest of mankind.

Plato was right: "Ideas rule the world." Passing from mind to mind, they transmit weakness or strength, defeat or triumph, to the thoughts and actions of men; and the realization of an individual, that his attitude and sympathies, in relation to a moral issue, may tip the scale of balance in the ominous moment of some fellow-sister's or fellow-brother's existence; sealing with terrible realism his or her moral or social fate, can not possibly fail to stimulate his mind to stronger efforts of self-control. I am my brother's keeper; not in act only, but in the far more potent sphere of thought.

Who doubts the terrible potency of thought and its fiery power to transfer everything it touches into its own element? Building or destroying, according to its character, thought constitutes the lever of human destiny, either raising the whole human situation to altitudes of vital and moral exaltation or sinking it to depths of soulless degeneracy and corruption. For, is it not true that before the glutton revels in his sumptuous, degrading living, he has first reveled in sumptuous, degrading thinking? And the damage and wreckage thus wrought in the world of mind; the moral contagion let loose in the motives and feelings of a defenseless humanity, depend for its deadly thoroughness on the moral receptivity or susceptibility of its victims. And as mental reactions are governed by the same principles as physical, the discharged thought-current will rebound with terrible energy on the mind in which they had their origin, sending the glutton still deeper into the mire of his bestiality, with the concomitant realization of sinking ever deeper into the clutches of raging passions and appetites. It is the monster, Frankenstein, turning loose its fury on the very author of its existence.

For, in the devolopment of the human will, through practices of altruism and high vital impersonal motives, lies the only guaranty for a continued evolution of humanity.

The Treatment of Rheumatism.

BY J. A. BURNETT, M. D.,
Dean Spring, Ark.

A good prescription in the treatment of rheumatism is as follows:

℞ Fl. Ext. Cimicifuga.....2 drachms.
Fl. Ext. Colchicum.....2 drachms.
Sodium Salicylate (true).....1 ounce.
Simple Syrup.....q. s.....6 ounces.

M. Sig.: One teaspoonful every two or three hours until the bowels act freely, and then every four to six hours as needed to keep the bowels active.

Cimicifuga is of value in most all forms of pains, and has been used alone with good results in many forms of rheumatism. It is a valuable alterative, and was Professor Marrow's favorite alterative nearly a century ago.

Colchicum is a useful remedy in rheumatism, when pushed to cathartic effect. When given too freely it will make a patient very sick. It has been used with success in many painful conditions.

Sodium salicylate is the most common remedy in the treatment of rheumatism, and will give good results in most cases, when a good preparation is used. The true sodium salicylate should be used, and not the synthetic product.

Another good remedy for muscular rheumatism is

℞ Fl. Ext. Arnica.....2 drachms.
Fl. Ext. Cimicifuga.....2 drachms.
Fl. Ext. Colchicum.....2 drachms.

M. Sig.: Three to six drops every two or three hours until purgation, and then every four to six hours.

Most cases of rheumatism can be benefited by good size doses of potassium iodide, after each meal, in addition to the other remedies being used.

Most all cases of rheumatism can be cured or greatly benefited by keeping the bowels a little loose with colchicum, giving large doses of true sodium salicylate and good size doses of potassium iodide. The diet, of course, should be carefully regulated, and the heart sustained with cactus, if needed. The use of superheated air is very important when proper apparatus is at hand.

[Written for the MEDICAL BRIEF.]

The Abbreviatory Treatment of Typhoid Fever.

BY H. TYLDESLEY, M. D.,

Member American Medical Association, Kentucky State Medical Association, Muhlenberg County Medical Society; Assistant Surgeon I. C. R. R., Etc.
Central City, Ky.

It is surprising to find how many errors are held regarding common diseases by many members of the medical profession.

Typhoid fever is no exception to this rule. It is commonly held by many otherwise excellent physicians that typhoid fever is in no sense capable of abbreviation. Another view is that typhoid fever is essentially and solely an intestinal disease.

While typhoid fever is regarded as, by the best observers, a self-limited disease, and while it is equally true that there is generally some intestinal lesions, it is far from truth to suppose that the morbid process is incapable of abbreviation, or that it is solely an intestinal affection. Hare, and the most able and conservative observers in the United States, and good clinicians in Europe, have concurred in this view. They believe the disease, by proper treatment, can be materially lessened in all particulars. They hold, also, that not only in the alimentary canal are we to look for lesions. They regard typhoid fever more as a general affection—having intestinal and other lesions as part of its process. In fact, the clinical history of the disease must lead all inquiring minds to this view. As a mere intestinal disease, all of the usual phenomena of the disease can not be rationally explained.

The abbreviatory treatment of typhoid fever does not consist in the employment of purgative drugs with a liberal hand. I believe in unloading the intestinal canal when necessary, but I believe that free purgation will often so sap the patient's strength that death will follow as a logical sequence. When I think there is an accumulation of fecal matter, I administer a saline. This is preceded by calomel only when there is evidence of biliousness. The abbreviatory treatment of typhoid fever consists in combating and preventing complications, and the conservation of the patient's resisting powers.

There is no drug nor serum that will bring the typhoid process to immediate termination. We must conduct the case so that the resisting powers will be crippled as little as possible. Let me view in order the problems that present themselves for solution in the average case of typhoid fever:

In nearly every part of the United States there is an element of malaria. This complicates typhoid fever very frequently. In fact, so often has malarial poisoning been found associated with typhoid fever that the disease has come, with many good practitioners, to be known as "typho-malarial fever." In the Southern States of this country this term is very generally employed. The best practitioners in these States use the term advisedly, because it means a common and distinctive morbid state, with which they are constantly in combat. In all cases we shall have to combat this malarial element, otherwise our patient will steadily lose ground. The remedy par excellence for this purpose is quinine. I prefer the hydrobromate of quinine, because it produces no tinnitus aurium, nor the nervousness that follows the employment of the sulphate. I give it in doses of five grains every four hours, and keep this up until I am satisfied that I can not prevent exacerbations of fever. I generally persist in the employment of the quinine for a week at least. Usually in this time the malarial element can be subdued.

High temperature entails great debility, and is most prejudicial to the patient. It is wise to control the temperature, if possible, and if it is kept below 102° F. the patient's best interests will be conserved. The means employed to accomplish these ends are antipyretic drugs and the baths—either cold or temperate. Antipyretic drugs are often the only safe means at our disposal for reducing high temperature. Often these drugs are needlessly employed, but I believe no capable, serious clinician would advocate their abolishment, or who would not say they have often proved a wondrously effective weapon. Very often having the patient sponged with tepid water will be sufficient to keep the thermometric reading low. But often we shall have to give an antipyretic drug. It has been claimed by some that the so-

called coal-tar derivatives have a depressing influence on the heart. But this is a statement which is largely untrue, and based on erroneous observations and hearsay. I have great faith in these drugs if they are used rightly.

Acetanilid, in doses of five grains, repeated every six hours, is a safe drug. The best observers among modern therapeutists will bear out my claims. I then use the tepid bath every four hours. If this does not reduce the temperature, I employ the antipyretics. A physician in a medical society told me that in giving antipyretics I only relieved a symptom, but I called his attention to the results which this unrelieved symptom would produce.

Intestinal antiseptics are valuable. I have found, after extended experience and experimentation, that no agent is more reliable or certain than salol, for this purpose. Three grains of this drug, administered every six hours, or oftener, if necessary, bring good results. Usually, when this drug is given in this manner, I find that my patient gets along without diarrhea and tympanites. The absence of these symptoms show me the value of this drug as an intestinal antiseptic, and I regard it as a very important agent in the treatment of the disease.

Stimulants *per se* are called for only when there is necessity to carry the patient through some tempestuous portion of the disease, or when the circulation shows irregularity or feebleness that is progressive. In such times we have a wonderfully effective agent—strychnine. Its action on the heart is quick, and it is reliable. In the prevention of failure of the heart this remedy is very valuable. When the cardiac irregularity or enfeebleness is progressive, or has obtruded itself upon the practitioner, the employment of strychnine will not prove satisfactory. In these cases we should depend upon alcoholic stimulants. Of these, brandy and whisky are generally the favorites. I continue the employment of the stimulants as long as there is any cardiac impairment. The dosage, both as regards the quantity of alcoholics and the frequency of administration, is to be adjusted to the requirements of the case in hand.

Cerebral hyperemia is a factor responsible for much lowering of the resisting powers. It induces headache, insomnia, convulsions, restlessness and consequential debility. To relieve this, tepid baths, repeated hourly, plus the internal administration of the bromides, are often very effective. In some instances of cerebral hyperemia the causative factor will be found to be high febrile action. In such cases acetanilid will be found a most effective agent. The application of cold cloths to the head, or the rubber coil, will be found very valuable in many cases.

Tympanites will rarely be present if we give salol, as already advised, but when this symptom manifests itself in aggravated form we shall employ turpentine internally, and apply the agent in the form of stupes externally. In some cases it will be found necessary to use a tube inserted far into the intestine to allow the gas to escape.

Diarrhea is due to dietary indiscretions, intestinal sepsis and other causes. These are to be corrected rationally. Bismuth and salol are the best general remedies to control the diarrhea. Opium, preferably morphine, is the best remedy in intestinal hemorrhage. It should be employed hypodermically. Ergot, tannic acid and other similar drugs are not so efficacious in intestinal hemorrhage as absolute rest, coupled with morphine.

Intestinal perforation is one of the gravest complications of typhoid fever. Without operation, it is universally fatal. In England and in this country, and on the continent of Europe, it is the custom to open the abdomen and repair these perforations in accordance with well-known surgical means. I think every case should be operated upon as soon as there is evidence of this condition.

So far I have said nothing about feeding. I am too conservative ever to allow my patients to have solid foods, as some advise. To my mind there could be no more serious mistake than to allow a typhoid fever patient to eat solid food. My own observation, that of Osler, and others, who give preference, experience have led to the deep conviction that only liquid food is to be employed. Milk, soup and soft-boiled eggs, and abundant water, are to be depended on constantly.

[Written for the MEDICAL BRIEF.]

Was Man Created Perfect?

BY REV. R. C. CAVE,
St. Louis, Mo.

Fifty years ago it was almost universally believed by the Christian world that, through a sudden and immediate exertion of God's creative power, man was brought into existence as a perfect being. The discoveries of science, bringing with them new conceptions of the divine methods, have caused many to modify, if not to altogether renounce, this old belief, but I think it is still held by a very large majority. A contributor to the March number of the BRIEF, who seems not disposed to altogether deny the doctrine of evolution, says: "As to whether God created Adam out of the dust of the earth, or whether He created a single primordial germ, or ten thousand of them, and developed Adam from the best of the lot, is of little consequence to us. We must assume that if God created man, or had anything to do with his creation, the result must have been a perfect and holy being." Why must we assume this? It seems to me as reasonable to assume that, if God had anything to do with the creation of a reptile, the result must have been a perfect and holy being; yet perfect and holy are hardly the adjectives we would use to describe some members of the reptile family. If the fact that God created something carries with it the conclusion that the something must have been perfect and holy, all things, from the most lovable to the most loathsome, must have been made perfect and holy; for all were created by God. But the discoveries of palæontologists have pretty conclusively shown that some things were not made perfect, to say nothing of their holiness. For instance, it can not be truthfully said that the oldest known animal of the equine type, the fossil remains of which have been found in the Eocene formation, was a perfect horse; for discoveries have revealed an ascending series of animals of that type, reaching from the ancestral form to the horse of the present, and showing gradual modifications of structure, from age to age. Instead of creating a perfect horse to start with, God made an equine animal with toes, instead of a hoof, and gradually evolved the horse from it. May he not have proceeded similarly in the case of man?

If, denying a similar procedure in the case of man, we claim that he was made perfect in the start, how can we account for his loss of perfection? The writer quoted above accounts for it by saying, in substance, that a principle of evil, of which "that old serpent, the devil," was "a sort of incarnation," existed in man's heart and tempted him to go wrong. But this, it seems to me, is an admission of man's imperfection. I am unable to see how a being with an evil principle in his heart tempting him to do wrong, can be perfect and holy. I can not conceive of God, the Perfect One, as having an evil principle in his heart, or as being tempted in any way. "God can not be tempted with evil;" and, if man was created perfect, he must have been, like God, above the reach of temptation.

Even the Bible account of creation, fairly considered, refutes the doctrine that man was made perfect. Instead of representing him as a fully-developed and perfect moral being, it tells us he had no knowledge of good and evil. When we can truly speak of one whose moral consciousness is wholly undeveloped, and who is so weak morally that he can not hold his own against the slightest temptation, as morally perfect, then, and not until then, may we truly say that the primitive man of the Bible was perfect.

The impartial student of history and nature can find nothing on which to base the belief that man was created perfect, and fell from his perfect state. On the contrary, he finds that, "Evidence points only to a primitive creature, without fire, clothes, language, tools, or houses; and with only this advantage—a dawning consciousness of his needs and wretchedness."

To the honor of his Creator be it said, that man, instead of falling below his first state, has risen above it. He was not first spiritual and afterwards animal, but first animal and afterwards spiritual. He began at the lowest point in the moral scale, and has slowly risen to his present moral condition. In all that goes to constitute true manhood, the man of to-day

is ages in advance of Adam, and incalculably nearer to perfection than the primitive being whom theologians describe as a paragon fresh from God's hand, with the stamp of divine excellence on his brow.

And I think we have reason to believe that man's progress will continue until he reaches the full measure of the stature of perfect manhood. If the writer from whom I qnoted in the beginning of this article will change his tense, and substitute "will be perfect" for "must have been perfect," I shall not feel disposed to take issue with him.

Suggestion, Violated Nature's Remedy.

BY ROBERT GRAY, M. D.,
Pichucalco, Chiapas, Mexico.

Nothing else calls up the furies from the abyss in the chastisement of perverse humanity so fast and unsparingly as violated nature. The counts in the indictme-t our common mother prefers against us are too familiar to the profession to require recapitulation. Every doctor knows more or less of their prolific harvests, many times to his regretful despair.

Our most rebellious and destructive diseases are but the mature fruitage of violated nature, as we are all beginning to learn and appreciate.

Yet the grave problem that confronts us at every nook and turn is not that involving remedies to dominate sequent disease, but, rather, that of preventing the gross violation of nature that produces the current ailments of mankind—vices that, if not actually popular, still such as are practiced with open impunity without shame—needless to enumerate as the profession understands them and realizes their consequences too sadly well.

This truism seems to be old as the everlasting hills—bequeathed from sire to son of ancient days, the sages and law-makers of the Israelites having known its pernicious dangers.

One of the ugliest vices in my long tropical experience, and one impossible to medicate successfully is that of eating dirt, salt paper or cloth, and very extensively practiced in tropical countries.

I treat it among children under ten or twelve years by the terrible influence of burying them alive; going to the extreme in the more obstinate cases of actually arranging a box in the house and impressing them with the conviction that the mere glance of my eye will detect the truth if the least particle of the favorite substance has been partaken. The effect is almost always magical, and the cure prompt and permanent. The only medicine is broken doses of podophyllin comp. and strychnine arsenate—laxative and tonic treatment. Possibly one in twenty baffles my every effort. But nothing else gives such cheering majority of victories.

New rum is another vicious article that prepares much trouble for all tropical practitioners; inebriates nearly all dying with well-developed pneumonia; the only show to save them being the abortion of the disease at its inception; not overdifficult, according to my experience, with aconitine progressively administered to saturation, such dominating influence being sustained by occasional fractional doses, with sufficient time between each; all of which the doctor on the battle-ground must determine, as I have found it impossible to establish any rule of practice otherwise for myself; two identical cases rarely obtaining.

I have been unable to cure permanently any current vice or habit by medication, and doubt seriously the contrary pretentions of others. Any treatment beyond the application of eliminative and tonic medication is practically worthless, save alone that of suggestion.

Here we stumble up against the grand majesty of mystery in the artful science of combating any violation of nature and relieving its consequences. Personal influence of irresistible power will win where drugs are our despair. I am master of the requisite degree for dirt-eating tots as stated, the susceptibility of the young and delicate minds being an auxiliary of inestimable value that renders them helpless in the presence of the ghastly specter of remedy. Naturally, a higher grade and more refined form of persuasive influence is necessary for adult transgressors.

I have found that there always remains a germ of primitive goodness, no

matter how seemingly beyond hope, inert in the shut and guarded bosom of the worst man or most depraved woman it is sometimes our lot to treat. To discover and probe to the quick the lethargic spot is the baffling secret that, alas! is too often beyond my ken. Once open, the victory, while uncertain, is still possible.

Those masters of suggestive therapy who are specially gifted or consummately trained by constant and assiduous practice should have much less trouble than what is my lot; with my time so imperatively demanded by the victims of tropical fevers, I am unable to indicate to masters what I, as an obscure student, do not understand sufficiently to employ successfully myself, while my limited experience amply justifies my faith that suggestion, ably manipulated, is the remedy for any vice or vicious habit, because I have attained some brilliant cures of almost every pernicious vice in the decalogue; too few, however, to permit me to pose as a practical authority.

It is probable, nevertheless, that with uninterrupted attention and persistent application I might cure more difficult cases than I have been able to dominate.

One great aid is the debilitated minds of such patients, the practical absence of self-will power, that renders most of them apt and pertinent subjects, readily pliable to the ruling sway of skillful suggestion. This is the cornerstone and foundation of my faith: that proper suggestive treatment will cure almost anyone whose physical anatomy has not been destroyed beyond redemption.

The attention of such a subject once arrested and held spellbound by a superior influence gradually yields, even with reluctant unconsciousness, and, little by little, surely, however slowly, the restraining sway gains the ascendancy in a degree that the patient obeys implicitly the mandate of the suggestor.

I am persuaded that there may be no definite limit to the possibility of suggestion, while it seems to me that there are spheres of suggestive power, some practitioners being peculiarly gifted with faculties far outstripping their humbler brethren, and that there are several grades of patients, some the less skillful suggestors can not benefit that those endowed in higher degree can influence propitiously.

As a matter of course, the science of suggestive therapy is, as yet, embryonic, though gestating by rapid process of development. If we have a true story of the healing powers of Christ, he was, probably, the only perfect master of suggestive medication the world has ever known.

Where the church dominates public sentiment or superstition wields a guiding sway over the ignorant, I have been able to draw coloring influence from Milton and Dante sufficiently powerful in allegorical figuration of the horrors of hell, and the sure destiny of the slave of vice to suffer all the dire consequences; such entail to deter the patient almost as effectively as the coffin and grave serve the turn of restraining dirt-eaters. But all this subterfuge of hell fire, the powerful leverage of the church in other days, is now obsolete and futile with more than half the Christianized world, the very priests of Rome, in many cases, and numerous Protestant preachers repudiating the doctrine, unfortunately for the cause of curing the vicious with such a remedy.

I am in a consistent Catholic region in every respect save alone that of a future life, the existence of a living soul in the clay tenement of man, which is almost unanimously denied; an unaccountable Christian inconsistency which negatives my favorite medication almost absolutely. I am unable to understand why such people baptize their children and go to confession under the conviction that all ends with the last gasp of this life.

Occasionally, when I have time, I play the role of preacher, and have persuaded several that the side of faith is the safer stand, and harmless, if untenable; yet such is not the proper province of the physician; nor has he, probably, any right to employ the thunder of the church as auxiliary medication, the treatment of vice being really the legitimate function of piety; yet it has drifted into or been adopted in the field of medical practice, where I do not scruple about the right to weapons with which I strive to combat its ravages, that send more than half of those who die in my field to premature graves.

But I desire to urge the profession not to confound the noble, almost divine prac-

tice of suggestive influence with basely groveling hypnotism, the anti-Christ of our sublime science of suggestive therapy, that is endowed with an inspiration and a faith above and beyond vulgar carnality, who knows in what degree of possibility? I, for one, vote against any measure of skepticism. I sometimes fancy, at least, that the dominating will-power of suggestion exercises a spell of enchantment over the spirit of the patient, through the solar plexus of the brain, and sets that inert element to repairing the dilapidated—may be disintegrating—anatomy, resulting in magical relief and miraculous cure to rival some of the attributes of Christ in the mere healing art.

Anyhow, and every way, the subject merits our profound study and earnest practice. We can not afford to ignore it. We are, for the most part, too liberal, too intelligent, too practical, too progressive, to scoff it. There is too much evidence of preponderating credibility in its favor—witnesses of the first rank in the profession. If we have faith in the science and can impart our faith to our patients in a responsive degree, some wonderful results may yet surprise the natives, whether of stupid or brilliant intelligence. I tell the more ignorant peon patients that the devil is present to carry them away, and that my province is to baffle and drive him out empty-handed; a certain victory if they will heed and obey me implicitly. Naturally, I do not omit what I regard as proper medication, striving to impress them with the conviction that any medicine administered should accomplish a desired modification of their affliction.

Somehow or other I fancy that my words and my medicine harmonize. Anyway, the result often surprises me in cases regarded as hopeless under every aspect of prognosis.

Destroyed by Fire.

The well known business house of Kress & Owen Company, New York, was visited by a serious conflagration, which practically destroyed their plant, but the same push and energy that has always been displayed in their business, overcame any serious delay in furnishing their goods. They can meet all demands for goods, and have thus established a record that is enviable.

Blisters in Pneumonia.

BY P. C. SUTPHIN, M. D.,
Canmer, Ky.

In the March issue of THE MEDICAL BRIEF there appeared a well-written and instructive article on Pneumonia, by Dr. Robert C. Kenner, of Louisville, the able and popular editor of the *Therapeutic Record*, a medical periodical somewhat recently established by him in the metropolis of his State.

Assenting to all that Dr. Kenner said in regard to the efficacy of his treatment in pneumonia, yet as he says of blisters, in the treatment of it, that he does not "frequently use them," as "interfering with the examination of the chest" and "opposed by many patients," so they should, according to this, be rather dispensed with, when possible, in our management of this disease.

But whilst this objection to the blisters, as urged by Dr. Kenner, is worthy of all consideration, and more especially as emanating from a source so learned and competent as himself, yet I would state that I have derived much advantage from their use in pneumonia, and, therefore, have been in the habit of regularly employing them in my treatment of this disease. I do not say that they are a *sine qua non*, or necessarily always indispensable in the treatment of it, as Dr. Kenner and others have shown them not to be, though it may be said that for the very long period, now, they have been held in the highest estimation by prominent and distinguished medical men of all enlightened countries for their superior efficiency and value in treating pneumonia. Carrying out the principle that "where the greater malady is fixed the less is scarcely felt," they, by producing it, may be a greater inflammation on the exterior cutaneous surface, than that just within; in this way draw the inflammation out, so to speak, from the lungs, where it may be difficult or impossible of cure, and transfer it to the external surface, where it could be both readily reached and cured. This, it may be said, is rather a savage way of treating disease; or, on the Indian plan of treating

chronic ulcer of the leg by turning it into a burn, and then curing the burn; so it is, however, the doctrine of *similia similibus curantur* can not, in such cases, as yet, be discarded as altogether a "thing of the past," and as such, to be "relegated to the rear." It was some fifteen years ago that I was called in consultation in a case of pneumonia with an old and able practitioner. The patient was a prominent and wealthy citizen, and probably some sixty-five years of age. When I saw him he had been waited on for some days by his attending physician, but gradually grew worse, till his condition seemed to hold out but little hope for his recovery. Dr. A., his physician, gave me the details of his treatment in the case; all of which was altogether intelligent and appropriate, and to which I told him I could add nothing but a blister to the surface of the affected side. To this he assented, and accordingly the blister was duly prepared and applied. I paid him but the one visit, but learned that after the action of the blister he began at once to get better, and soon was well. Seeing him after this, he told me that he never had anything to do him as much good as the blister; that as soon as it began to "draw" he felt better, and continued so until he got up. He was certain, he said, that it saved his life, as nothing before that had done him any good. It is probable, however, that the treatment of his case before that had all due effect in staying the disease, at least, if it didn't cure it, whilst all that was needed was the blister to give it the "finishing touch," and thus complete the cure.

As before said, I have been in the habit —and, I may add, since my earliest practice, now a good many years ago—of employing blisters in my pneumonia cases, with the result that I have always had superior success with them, and have often seen the disease more or less readily yield to their action, when other treatment, by internal medication, had little or no effect on it. It is true, as Dr. Kenner observes, that they interfere, to a greater or less extent, with the examination of the chest, by percussion, more particularly, however, though, whilst this is so, yet as the condition of the lungs can be fairly tested in other ways than by percussion and auscultation, when these are interfered with—that is to say, told by the pulse-beat, bodily temperature, breathing, etc.—so the more direct examination of the chest under the circumstances of the blister; the latter, it may be of especial value in the case—I say this examination might be better under these circumstances; give place to the higher good that might be done without it by the blister.

In regard, further, to the use of blisters in pneumonia, I would state that I have employed them in cases of the old and young, excluding, however, infants, and never failed of good results from their use. I remember using them once in a case of double pleuro-pneumonia in an octogenarian lady; applying the blister to the left side first, which soon drew the inflammation without, leading to a beginning cure of that side. Thinking that blisters on opposite sides, at the same time, might prove antagonistic, or, rather, fighting each other, and thus do no good, I deferred applying the blister to the right side for several days, trusting to internal treatment in the case; whilst, however, that side still continued bad, with no improvement in its condition. Now applying the blister to it, it soon, under its action, began to improve, as with the other side, and in a short time was the source of no further trouble.

So much, rather, in the way of the *breviter in modo*, as to the blister in pneumonia, as looked at from my standpoint of view. Of course, I could not, in the mere paper like the present, go into any *in extenso* details or mention of it, such as quoting from writers on the subject, citing the favorable opinions of medical friends in regard to it, or presenting further views of my own as to it, though viewed from the standpoint of proof and efficient service, the blister, so far has stood as one of our most potent agents in the treatment of pneumonia.

In concluding this imperfect paper, I would state that none of it was designed in the way of criticism of Dr. Kenner's very excellent and instructive article, but simply to present my views, in kindly little issue with him, on the subject of the blister, which latter, he thinks, as interfering with the proper examination of the chest, should be treated with suspicion, as

in that way it may be doing harm rather than good. Of the rest of Dr. Kenner's paper, in the meantime, well written, lucid and practical, it furnishes a most intelligent and efficient guide to us in our treatment of pneumonia.

[Written for the MEDICAL BRIEF.]

Neuroses.

BY W. T. MARRS, M. D.,
Peoria Heights, Ill.

A neurosis is an affection whose cause is unknown, or of obscure origin. Scientists and pathologists are disposed to regard as unimportant those diseases in which diligent research has failed to discover an anatomical basis to account for them. As a matter of fact the scalpel, reagent and microscope have failed to give us much information in the troublesome class of ailments known as neuroses. The search for causative factors in neurotic conditions is always a tentative procedure. There are many and varied conditions to be investigated. Heredity plays the strongest role. Next the patient's occupation, habits and general environment need a careful scrutiny. There may be constitutional derangements at the bottom of many stubborn neuroses. Among these are constipation and auto-toxemia, abnormal constituents in the urine, and in general a disturbed or perverted metabolism. Causes of a more direct reflex character are worms of the various sort, gall-stones, eye-strain, uterine affections, adhesions, mechanical pressure, etc. In the typical neuroses and psychoses none of the abnormal conditions named are likely to be present. The fact that no cause in the way of a distinct entity can be found in any given case should not deter the physician from giving the matter painstaking attention. It should be borne in mind that the symptoms are *real* to the patient, whether they be scientific or not.

Hysteria is one of the most striking examples of this type of affections. As hysteria is very rarely written on a death certificate, many physicians are disposed to treat these cases with good-natured contempt. It is true that the correct management of such cases involves much study, but, after all, they deserve careful consideration in view of the grave sequelæ that may ensue, as well as the damage to posterity. It is at the crises of a woman's life that this condition is most manifest, *e. g.*, puberty, marriage and the climacteric. If the woman has not judicious treatment she may suffer more or less all her life. If she continue to bear children while in this state of nerve instability, the same nerve impress is likely to be stamped upon her offspring. Hysterical patients whose antecedents were highly neurotic are prone to become victims of insanity. In the treatment of hysteria little medicine should be used. These patients are very easy to acquire drug and medicine habits, and the constant taking of something has a mental influence that helps to perpetuate the trouble.

Neurasthenia, hypochondriasis and melancholia are only functional conditions, but they may be accountable for untold suffering. They are conditions in men that are almost analagous to hysteria in females. There may not be discernible anything to account for the patient's aches and vagaries, but we have no means of measuring subjective symptoms. We can not deny the fact that the patient suffers. In the way of treatment, if we can but prevail upon them to let quacks and quack literature alone, we have accomplished much good.

Migraine may usually be regarded as a neurosis, notwithstanding the volumes of wisdom that have been written on this subject. In nearly every case of severe headache recurring with some degree of regularity, there is to be found a family history in which the nerve element showed decided impairment. The paroxysm attending migraine relieves pent-up energy in certain nerve cells and centers, and the victim enjoys comparative freedom from pain until another attack recurs.

Epilepsy is, in its incipiency, to be classed in the same category with migraine. It is true that sometimes in epilepsy we find distinct reflexes that may be put down as factors of causation, but if there were not inherent tendencies of psychic origin it would require a powerful reflex to produce a nerve storm in the way of an epileptic seizure.

The remarks concerning epilepsy apply with about the same accuracy regarding chorea. Both are neuroses, at least in their incipiency.

Nervousness, insomnia, ill-temper, despondency, pessimism, etc., may hardly be dignified by being called disease symptoms, yet they are unnatural, and, therefore, unphysiological. They may make one's life as miserable as actual disease.

The treatment of the class of affections so briefly outlined in this article may involve a therapy that is far-reaching in scope. Certain functions may need correcting. In many cases the general health is not at fault. The environment must be made as congenial as possible. The old stereotyped medical advice, viz.: To quit everything now indulged in, and do the very opposite, here finds a certain degree of favor. The employment should, so far as possible, be along lines suited to one's preferences. Appropriate literature may serve a good purpose. On the whole, the patient must be educated into a new way of living and thinking. He must interest himself in things in a way that will cause him to forget himself and his own importance, at least for a part of the time. In all neuroses psycho-therapy may be used to great advantage. Its employment as a distinct remedial agent may not be so well accomplished as by a vein of it incorporated with all methods and measures. In no other class of ailments can the agency of the mind in some way be so successfully employed.

[Written for the MEDICAL BRIEF.]

Physical Exercise.

BY H. D. FAIR, M. D.,
Muncie, Ind.

The health and usefulness of our material bodies and the happiness and serenity of our lives, to a certain extent, depends on effort (exercise), which may be defined as labor or exertion. The latter may be either physical or mental, and applicable alike to the brain or muscles of the body.

Exercise may be considered under three general divisions: that which is an essential factor in the earning of our daily bread (labor); that which may be employed or forced for the purpose of accomplishing a certain object (gymnastics), and that which is taken as recreation (play). An agreeable change of occupation may temporarily, and, to many persons, does, take the place of recreation.

In order that symmetrical development and harmonious functions result from such exercise, each and every muscle in the body demands its full quota of work. Spasmodic attempts should not be encouraged, and protracted effort along particular lines only are never satisfactory. We may admire the blacksmith's strong right arm, or the muscular calves of the bicyclist, but they may belong to one-sided individuals; the former may have weak legs, and the latter a flat chest. The beautiful body is one that is equally developed in all its members. No part should ever be conspicuous because of either deficient or excessive development; therefore, the forced exercise should be that which best calls into play the muscles previously left inactive, because of the peculiarity of the ordinary daily routine, and this object should be kept in view when the selection of supplementary exercise is made.

The person who sits all day at a desk or operates a bench machine should take long walks before going to bed. The individual whose occupation enforces a cramped position, should, whenever opportunity presents itself, attempt over-correction; that is, the opposite extreme should be employed, for, in this way, the body is stimulated or assisted in the effort to maintain an equilibrium when in a state of repose.

The great advantage in learning to have the right and left hand equally skillful and completely under the control of the will, needs no argument to demonstrate. I believe all children should be taught to use both hands, either when writing or at work; this not only makes the individual more proficient, but frequently accidents happen depriving one of the use of the right hand, and in which the degree of helplessness would be much less had the unfortunate one early learned to use both hands equally well.

No person starting in on a course of gymnastics should attempt to keep pace with a well-drilled class. All stunts should be progressive. The point of mild fatigue

should never be passed, especially by the beginner.

For those whose duties are such that an additional routine in gymnastics is advisable, an expensive or complicated apparatus is not essential. A broom-stick or a kitchen chair can be used to good advantage. A horizontal bar, either swinging or stationary, can be conveniently arranged with little or no expense. Two long-necked bottles, like those used for beer or champagne, partially or completely filled with water or sand, make satisfactory substitutes for dumb-bells or clubs.

Circulars describing the various exercises and illustrating the use of apparatus can be procured at stores where gymnasium or sporting goods are sold, or may be ordered through your druggist or stationer.

[Written for the MEDICAL BRIEF.]

Bacteria Germs or Bugs Are Not the Only Cause of Disease.

BY ALFRED J. WEED, M. D.,
Granby, Conn.

Germs, bacilli, or invisible insects, as they are sometimes called by the laymen, are of less active danger to human beings than one other producer of morbid conditions—the mind.

With a good, robust mind, which is of itself antagonistic to disease in a vigorous body, one may laugh at a million germs or bugs, for they are harmless, except nourished by conditions suited to their growth, and these most favorable circumstances only are allowed to exist because of the absence of the acts of a good mind.

When one thinks disease, look out for danger. A scientific physician—and, deplorable as it seems, not all assert—well knows and will have to admit the fact to his friends and patients, and, accordingly, teach such as are willing to learn.

People are very slow to accept this fact, this well-meant advice, and to profit by it, and this seeming indifference may come from a feeling that the fact is not sufficiently proven, yet in such a case the person receiving such advice must consider the professional advice as coming from one able to know even if absolute proof is wanting. Things, oftentimes, must be accepted as facts, in the absence of absolute proof. Where two theories are advanced and neither absolutely proven, the people must cleave unto that which seems most plausible, eschewing the others; therefore, when a professional man proclaims one theory more logical than the other, why, we must accept it.

If a thought can, in an instant of time, hasten or retard the action of the heart, if it can dilate or contract the blood vessels, causing a rush of blood to or from any part; can increase or diminish the secretions of a gland, if it can turn the hair gray in a single night, can force tears from the eyes, can produce great bodily weakness, even in a twinkling of an eye, yea, even carrying instant death, then why is it not logical to conclude, without argument, that it may produce derangement, even continued derangement of the physical organism, which we call disease.

Instances are many where the acts of the mind not only produce disease, but it perpetuates it. Indeed, in the experience of any busy practitioner of medicine, can it not be said that many morbid affections are caused by the acts of the mind? Even the majority of cases of illness are produced, alarmingly, by the thoughts. It is not unusual for some one returning from the funeral of a loved one to be taken ill and, in a few days, to follow that one to the grave. We ask, What is it that causes this death? Depressing thoughts.

A mother hears of some terrible calamity having befallen her child. She goes into a collapse, fever follows, and that mother may, for days, linger even unto death.

A man is seated at a banquet table, full of health and happiness, blessed in every way, his face beaming with exquisite pleasure and good cheer. A message is brought to him that his wife and little ones have been drowned in a flood. He turns pale. His beaming face is now as white as death. His appetite has departed. He falls from weakness. All the functions of the body are deranged. A doctor is called and the disease is diagnosed. But is it not the fact, is it not true, that the diseased condition was the result of what he thought? Possibly, some

will say that some organ in that body was in a morbid condition, and the pathological process was dominant, as far as progressiveness was concerned. Even so, were it not for the overwhelming effect of that terrible mental impression, the man may have survived for many years; therefore, the power of the mind over the body was the immediate cause of death.

A fit of anger will cause the most wonderful train of symptoms. After such a condition has operated, the functions of the glands are impaired. Many instances I have observed where an infant nursing its mother just after she has been engaged in a violent quarrel will become ill, and even die.

Every wise physician has many instances which he might recall where the mind has great effect on the body, and it seems to me a fact beyond the peradventure of a doubt that if impressions of the mind produce such results as herein mentioned, the same mind may, if continued morbid, be a producer of disease, even more of a producer than a million germs floating in God's clear air.

[Written for the MEDICAL BRIEF.]

The Proper Diagnosis.

BY E. B. HOUSE, M. D.,
Washington, D. C.

"Good morning, my friend," said old Doctor Wise,
As he took off his specks and mopped out his eyes.
"What's the trouble this morning, with you, Mr. Jones?
Is it your stomach, your back, or your bones?"
Mr. Jones, racked with pain, not a little surprised,
Began, in this manner, to tell Doctor Wise:
"My head is near bursting, I scarcely can see.
Now, Doctor Wise, what's the matter with me?
Is it the measles, the mumps, or the gout?
That's bothering me so?" Mr. Jones yelled out.
The Doctor, harassed with a little distress,
Said: "You see, Mr. Jones, we doctors don't guess.
And before I can venture to positively say,
You'll have to wait for one more day."
Mr. Jones closed his eyes with silent content,
For he knew Doctor Wise always said what he meant.
The morrow arrived, and the Doctor, so true,
Returned with his satchel to see the case through.
The patient was aching from his feet to his head,
And declared to the Doctor he wished he was dead.
The Doctor inquired: "Have new symptoms appeared?"
And when told that they had, said: "It's just as I feared.
Your tongue is all coated, your pulse ninety-four,
But before I can tell, I'll have to know more.
Is your appetite good? Do you sleep well at night?
Are your nerves unstrung? Do your kidneys work right?
Your respirations are twenty or more,
And it seems that that cough would make your chest sore.
And you say that you vomit just after each meal,
And the sores in your mouth refuse to heal.
All right," said the Doctor, as he arose;
"I think by tomorrow I can diagnose.
For surely by then the case will be clear.
Rest easy, my friend, and have no fear.
Take no more of those powders; no more of those drops,
But go on with this till your headache stops.
This opiate will relieve all your pain,
And none of that cough, I'm sure, will remain."
"But, Doc," said the patient the following day,
"The name of my ills you have failed to say."
The Doctor looked wise, as he reared back his head:
"You ought to be thankful, sir, you're not dead.
But, to tell you the truth, without disguise,
I don't know," said good Doctor Wise.
"But this much I'll say, and say without fear,
Had you not sent for me you would not be here."
The patient relapsed into silent repose,
And gained by the rest of a short little dose.
And when he awoke he was there all alone;
Our friend, Doctor Wise, had departed for home.
And when Mr. Jones went down with a will
To pay Doctor Wise his little bill.
He asked how the Doctor had managed to save
Such a sick man from an early grave.
Doc said, with a smile: "To keep men from dying,
All that we do is to keep on trying.
I gave you hypnotics to settle your brains;
To keep you quite still and ease off your pains.
You had not rheumatics; it was not the gout,
For salicylates always drive such things out.
It wasn't a fever; it was not the chills;
For it didn't respond to those quinine pills.
I gave you some pepsin; some calomel, too;
And if you was bilious, that pulled you through.
Those strychnine tablets were for your heart,
And toned your system from the start.
The arsenic and iron were for the blood,
And, no doubt, did a great deal of good.
I gave you the bromides, for you was unnerved,
And I'm sure that they their purpose served.
And now, Mr. Jones, the next time you're sick
Send for Doctor Wise, and he'll do the trick."

[Written for the MEDICAL BRIEF.]

Absorbing Uterine Tumors.

BY J. A. HOUSER, M. D.,
Indianapolis, Ind.

The development of surgery has been so great and rapid in the last few years that it has crowded medicine from some territory justly its own. Indeed, this is the age of ripping women up, and many a one goes under the knife who would fare far better in the hands of the physician than on the operating table. With some surgeons the desire to operate becomes a mania that none but the strong, cool, well-balanced mind can control. Time was when the French surgeons were the butt of jokes and subject to derision because of their thoughtlessness and recklessness in the use of the knife. France monopolizes this opinion no longer; American surgeons are at least dividing such surgical honors.

Many of the tumors removed by the knife, often with anything but satisfactory results to the patient, could be successfully treated by the physician. I have no hesitancy in declaring my confidence in the belief that at least eighty per cent of all uterine tumors can be absorbed entirely or lessened and the growth permanently checked by medical treatment. This I have demonstrated in the treatment of such growths for many years. My experience is only a short story of treatment, neither intricate nor varied. But a few conditions must be observed. Not only the kind of tumor must be taken into consideration, but also the temperament of the patient, since the remedies I use can not be taken in the same way by patients of different organic condition. My sheet anchor and that which I use in some form, is potassi iodid and mercury, generally the bichloride. The nervous, delicate woman, with a weak stomach, will not always tolerate the iodid, but, combined with the bichloride, often fattens on it, while the patient with the sanguine temperament can not long tolerate mercury in any form, at least harmlessly, unless safeguarded by an alkaline. The billious temperament, with black hair and yellow or tawny skin, lean, spare, poorly nourished, will not eliminate the remedies readily, and, if not properly administered, will be retained too long in the system, causing much harm. In such cases glycerin is a much better vehicle than the time-honored syr. stillingia. With these hasty remarks I will briefly mention a very few of the many cases I have treated in the last twenty-five years:

Mrs. S. T., of Marion, Indiana, aged forty-four. Fibroid so large the abdomen more than suggested full time in pregnancy. Severe hemorrhages; bowels constipated. The lymphatic temperament favored both remedies, which were given in syr. stillingia, the iodid in five-grain doses and the mercury one sixty-fourth grain to the dose. After nine months the tumor was entirely absorbed.

Mrs. C., Bluffton, Indiana, could not tolerate the remedy as well as Mrs. T., and, during the course had an attack of pneumonia which necessitated a discontinuance of the treatment for some time, as lung complications followed; but after more than a year her tumor, which was larger than a four-quart measure, yielded and disappeared.

Mrs. A. P., Chanute, Kansas, had a tumor of large depressing proportions. In this case the mercury was omitted and bromide potassium was substituted. She was entirely relieved in eight months.

Mrs. G. M., Spencer, Indiana, required but about six months' treatment to relieve her of a large uterine tumor. Her temperament was such as to tolerate large and continuous doses of both drugs. In all these cases saline or other mild cathartic was freely given. The iodid was seldom given in doses of more than five grains, and the mercury never over one thirty-second grain.

If the drugs have the desired effect the tumor will, seemingly, be larger at the end of the first month than when treatment was begun, but diminish rapidly after that. Sometimes, however, the growth will remain unchanged for a considerable period, then diminish with great rapidity.

A lady from Barton County, Missouri, who had a large tumor, took this treatment patiently for eleven months without noticing any perceptible change in the

growth. Then it disappeared more rapidly than any I had ever heard of before, but not until I had pushed the drugs to the limit, and the lymphatic had become tender, the gums irritated, and many small pustules had appeared on the skin.

I have found the nervo-sanguine temperament the hardest to treat, and the one most likely to result in failure. The bilious lymphatic yields the most easily.

In conclusion, I would say a word as to the diet of the patient while under treatment: Salt should be used very sparingly, if at all; acids should be avoided; meat not more than once a day. Milk and cereals are the best foods during this treatment.

The patients who would sit as directed, before a window, letting the sun shine upon the back, for hours, showed better results than those who did not do so.

204 North Alabama Street.

Examination Questions and Answers Maryland Examining Board, June 20-23, 1906.

(Continued from Page 318).

SURGERY.

1. What are the general principles governing the treatment of fractures at or near joints?

ANSWER.—Examine carefully to see if a dislocation exists. Also anesthetize patient if in doubt. Carefully adjust fragments, make passive motion early, and inform the patient that he will probably have a stiff joint. Put up limb in position which will be most useful to him if it becomes stiff, *i. e.*, elbow joint. Put up forearm at nearly a right angle with arm, and midway between provation and supination.

2. What conditions require and what is the usual method of performing (a) thoracentesis, (b) resection of ribs?

ANSWER.—(a) Conditions requiring thoracentesis: (1) to remove a collection of serous fluid which is producing symptoms; (2) to diagnose the nature of the fluid. Under thoroughly aseptic conditions the aspirating needle is plunged into the pleural cavity at the fifth interspace, just in front of the angle of the scapula, the patient being in the semi-recumbent position. The intercostal artery is avoided, and care is taken to avoid injuring the lung. The fluid is drawn off preferably into a bottle by a pump, and is done rather slowly in order to avoid cough and syncope. If the patient becomes very faint the operation is abandoned. It is best to withdraw large accumulations in installments. (b) Conditions requiring resection of ribs: (1) Empyema for drainage; (2) Exploratory operations on parts covered by ribs; (3) Fracture of ribs injuring internal organs; (4) Tumors or necrosis of ribs. Usually remove portion of sixth rib in midaxillary line. Incision over middle of rib, about three inches in length. Divide periosteum in same direction, separate it from bone, being careful not to injure artery. The bone is divided with forceps or a Gigal saw, about an inch being removed. Artery is ligated at each end of the incision, periosteum is removed, and pleura opened, if indicated. The object of removing the periosteum is to prevent the too rapid reformation of bone. The incision may be enlarged, and two or more ribs resected if necessary.

3. Give the treatment of a sprain of the ankle joint.

ANSWER.—In mild sprains Tibney's method of applying adhesive plaster to the joint is best. The patient may walk at once. This prevents stiffness, and the pain soon disappears. More severe sprains require rest and elevation, and the application of cold, although heat sometimes will give greater comfort. Massage should begin on the second day. By the fifth day the acuteness of the pain has passed, and the adhesive plaster dressing may be applied. Massage should be used, and the patient allowed to get about as much as his comfort will permit.

4. (a) Give the differential diagnosis between chancre, chancroid, and herpes preputialis; (b) Give in detail the proper treatment of each.

ANSWER.—Chancre due to contagion from a chancre, a syphilitic lesion, or blood or pus from a person having syphilis. Chancroid due to contact with pus from a similar sore. Herpes preputialis due to mechanical or chemical irritation, or occasionally to a cold or fever. Incubation of chancre, ten days to six weeks. No incubation period for chancroid or herpes. Chancre usually single, chancroid and herpes usually multiple. Chancre superficial or elevated, chancroid punched out, herpes superficial. Surface of chancre smooth, shining, red; chancroid rough, uneven. Secretion of chancre scanty, serous, autoinoculable with great difficulty; secretion of chancroid abundant, purulent, readily autoinoculable; herpes, moderate secretion, autoinoculable with difficulty. In chancre, induration almost always present, in chancroid rarely present. Chancre, no pain; chancroid and herpes, very painful. Chancre usually heals spontaneously, second attack rare; chancroid often extends, no protection against second attack; herpes may spread, but usually heals promptly. The bubo of a chancre is constant, or herpes is rare, and of chancroid occurs in one-third of cases. The only positive diagnosis of chancre is in the secondary symptoms of syphilis. *Treatment*—Chancre, do not cauterize, unless it is phagadenic. Soak in warm salt water twice daily, and spray with fifty per cent hydrogen peroxide. Dust with equal parts calomel and bismuth. Constitutional treatment

only after appearance of secondary symptoms. Chancroid, clean with peroxide, cauterize as often as necessary with carbolic and nitric acid. Moist dressing of bichloride or black wash. When granulation begins, dress dry with calomel and bismuth. If phimosis exists, make dorsal incision or circumcize. Herpes preputialis, clean and dress with calomel and bismuth or boracic acid.

5. Stating your reasons, give what you consider to be the most suitable suture material for (a) anastomosis of the intestines; (b) uniting the peritoneum; (c) muscles of the abdomen; (d) closing skin.

ANSWER.—(a) Fine silk, because of its strength and slow absorption. (b) Medium-sized catgut, because it absorbs in a week or ten days. (c) Catgut, because of its absorbability. (d) Catgut, if a subcuticular stitch is taken, because of its absorbability, but silkworm gut, if through-and-through stitches are taken, because it is less liable to become infected. Of course, I would choose none of these sutures unless their sterility was assured.

6. Give the treatment of severe shock after severe injury or after a major surgical operation.

ANSWER.—Treatment of severe surgical shock: Raise feet and lower head, unless position causes cyanosis. Wrap patient in blankets, surround with hot water bottles, taking care not to burn him. Ordinary stimulants do not seem of much avail, but may be tried; either brandy, strychnia, digitalis, atropin, hypodermically. Opium is contraindicated. Hot and stimulating rectal enemata are valuable, i. e., ammonium carbonate, twenty gr. in one quart hot water, or hot coffee and whisky, two ounces. Bandage extremities to keep most of blood in brain. Apply mustard plasters over heart and spine.

PATHOLOGY.

1. Define the following terms: (a) Coccus, (b) bacillus, (c) spirillum, (d) faculative anerobe, (f) name one anerobic organism.

ANSWER.—(a) A spherical shaped bacterium. (b) A rod-shaped bacterium. (c) A spiral or cork screw shaped bacterium. (d) A bacterium that grows only in the absence of oxygen. (e) One that grows best without oxygen, but will grow in the presence of oxygen. (f) Tetanus bacillus.

2. (a) Name the pathogenic cocci. (b) Give the morphology. (c) Method of staining of each. (d) Name the varieties usually found in the following diseases: (1) Fornuculosis, (2) tonsillitis, (3) purulent salpingitis.

ANSWER.—(a) Staphylococcus pyogenes aureus, albus and citrens, staphylococcus epidermidis albus, streptococcus pyogenes, gonococcus, diplococcus intercelluloris meningitidis, micrococcus letratgenus, pneumococcus. (b) The staphylococci are in irregular masses, or clusters, like bunches of grapes; streptococci are in chains, gonococci are shaped like coffee beans, diplococci are in pairs, of which the pneumococcus and diplococcus meningitidis are types. (c) They are all stained with Loefler's methylene blue, the process of which is as follows: Make a film of the bacteria upon a clean cover slip, dry and pass three times through the flame to fix, pour on the methylene blue, wash off after a quarter of a minute, dry, mount in xylol balsam, and examine with one-twelfth oil emersion objective. (d) (1) Staphylococcus epidermidis albus. (2) Staphylococcus, streptococcus and pneumococcus. (3) Gonococcus.

3. (a) Describe in detail the process of cavity formation in a case of tuberculosis of the lungs. (b) Give the morphology of. (c) Describe in detail the method of staining of the tubercle bacillus. (d) Name two other bacilli with similar staining properties.

ANSWER.—(a) Individual tubercles from which ultimately undergo caseous mass enlarges as the tubercles do, and finally coalesces with adjoining ones forming greater masses of a cheesy necrotic substance which breaks down, sloughs out, and forms cavities. (b) The tubercle bacilli are slender, rod-shaped, sometimes beaded, either straight or curved, bacteria about one-half micron in diameter and from three to five in length. (c) Make a thin film of the suspected substance upon a cover slip with a sterile platinum loop, dry, fix by passing the cover slip three times through the flame with film side up, pour upon it Ziehl's carbol fuchsin, steam for three or four minutes (do not boil), wash off with water, decolorize with ten per cent mineral acid, wash in water, counterstain with methylene blue, wash in water, dry, mount, examine with one-half oil emersion. (d) Hay bacillus, smegma bacillus.

4. Describe the pathologic changes as regards the urinary tract one would expect to find in a case of hypertrophy of the prostate of long standing.

ANSWER.—The median and posterior lobe undergoing a hyperplastic condition with the remainder of the prostate, infringes upon and sometimes closes up the urethra preventing urination.

5. Describe microscopically the changes one would expect to find in the appendix and surrounding structures in a case of catarrhal and one of gangrenous appendicitis, respectively.

ANSWER.—In catarrhal appendicitis there is enlargement and congestion of the appendix with dilatation of blood vessels leading to the organ, frequently a mucopurulent fluid in its lumen, and no adhesions or pus. In gangrenous appendicitis, the pathological changes would depend entirely upon the progress the gangrene had made. In the early stages there would be a violently inflamed and congested condition of the appendix, and a dark spot would appear at the focus of inflammation. As the disease progressed this spot would enlarge till death of the whole appendix would take place. Violent suppuration then begins, a cellular exudate takes place in the surrounding tissues, which forms adhesions and a protective wall against the forming pus. This process progresses until

only floating debris of the gangrenous appendix is found in the pus.

6. Give a gross and microscopic description of a cross section of myomatous uterus. In what localities is this species most frequently found?

ANSWER.—This question is not correctly stated. A myoma of the uterus microscopically has a firm whitish appearance, is tough and fibrous, and looks very much like normal uterine tissue. Microscopically it has spindle-shaped cells with cigar-shaped nuclei, with less intercellular substance than a fibroma. Myomata are found principally where there is normal non-striated muscle.

CHEMISTRY.

1. Define the terms: (a) Element. (b) Compound. (c) Mixture. (d) Explain the use of the suffixes: ous and ic.

ANSWER.—(a) A substance composed of only one kind of atoms. (b) A substance composed of different kinds of atoms chemically united. (c) A physical association of different substances. (d) ous means that the element to whose name it is joined occurs in a greater proportion; ic means that the element to whose name it is attached occurs in a lesser proportion.

2. (a) State the chemical composition of atmospheric air. (b) What is the difference between expired and inspired air and explain how this is brought about?

ANSWER.—(a) Air is a mixture of oxygen, twenty-three per cent; nitrogen, seventy-seven per cent, together with small quantities of water, carbon dioxide, ammonia, argon, etc. (b) Expired air is richer in carbon dioxide and poorer in oxygen than inspired air, the difference being due to the oxidation of the tissues by the oxygen taken into the blood, thus forming carbon dioxide, which is brought away by the venous blood and discharged into the lungs, the air to be expired.

3. (a) State the properties of good drinking water. (b) What are its most dangerous impurities and why? Describe the methods in use for its purification.

ANSWER.—(a) Clearness, absence of odor, and absence of organic matter. (b) Organic matter indicates bacteria. (c) Boiling and filtration.

4. (a) Give the chemical definition of a simple ether. (b) Give the chemical constitution and the physical and chemical properties of sulphuric ether. (c) Is this term a correct one, and why?

ANSWER.—(a) Oxides of hydrocarbon radicles. (b) "Sulphuric Ether" has a formula $(C_2 H_5) O_2$. Ether is a clear, volatile, inflammable liquid, a good solvent for many resinous substances. (c) The name sulphuric ether is incorrect, because neither sulphuric acid nor its radicle SO_4 enters into the composition of ether. The correct chemical name for the official ether is ethyl oxide.

5. (a) What, chemically, are the vegetable alkaloids? (b) State their characteristics and give the effect of solvents on them and their salts.

ANSWER.—(a) Vegetable alkaloids are basic carbon compounds capable of joining with acids to form salts. (b) They are generally white, bitter, crystals, less soluble in water than are their salts.

6. (a) Suppose a specimen of urine of normal specific gravity and of ether neutral or faintly acid reaction shows, on boiling, a precipitate. What substances may this indicate? (b) How are they to be differentiated?

ANSWER.—The approach toward the alkaline reaction is due to either the elimination of fixed alkalies derived from food, or from alkalies resulting from the decomposition of urea. (b) Litmus paper turned blue by the fixed alkalies remains constant on drying, while litmus paper rendered blue by the alkalies derived from urea resumes its red color.

MATERIA MEDICA.

1. Give the composition of (a) compound cathartic pills; (b) black wash; (c) Dover's powder.

ANSWER.—(a) Compound extract of colocynth, 8 per cent; mild mercurous chloride, 6 per cent; resin of jalap, 2 per cent; gamboge, 1.5 per cent; diluted alcohol, q. s. (b) Mild chloride of mercury, 7.5 of 1 per cent; water and solution of lime, each q. s. (c) Ipecac, 10 per cent; powdered opium, 10 per cent; sugar of milk, 80 per cent.

2. (a) Give the Latin title of paregoric; (b) name all its constituents. (c) Give the amount of the principal drug in one ounce of the mixture.

ANSWER.—(a) Tinctura opii camphorata; (b) powdered opium, benzoic acid, camphor, oil of anise, glycerine, diluted alcohol. (c) 1.82 grains.

3. (a) What is the official name of calomel? (b) What drugs are incompatible with it and why?

ANSWER.—(a) Hydrargyri chloridum mite. (b) Acids, acid salts, alkaline carbonate, lime water, ammonium chloride, potassium iodide, ferrous salts, sulphur, antipyrine, antimony sulphide. Because these drugs react chemically with calomel, forming poisonous or undesirable compounds.

4. (a) Give the botanical name and (b) official preparation of digitalis, with dose of each.

ANSWER.—(a) Digitalis purpurea. (b) Extractum digitalis, one-fifth grain, fluidextractum digitalis, one minim; infusum digitalis, two fluid drachms; tinctura digitalis, fifteen minims.

5. Name the official vegetable acids.

ANSWER.—Acetic acid (in three strengths), benzoic acid, salicylic acid, camphoric acid, gallic acid, hydrocyanic acid, tannic acid, tartaric acid.

6. Give the source of (a) acetanilid, (b) caffein, (c) salol.

ANSWER.—(a) Coal tar derivative. (b) alkaloid from coffee and tea. (c) Salicylic ester of phenol.

THERAPEUTICS.

1. Give the general rule for calculating doses for children.

ANSWER.—Young's rule, which says, add twelve to the age and divide by the age to get the denominator of the desired fraction, the numerator of which is always one.

2. What are the modes of administration of medicines? How does dosage vary in each with that of the mouth?

ANSWER.—(a) By the mouth and stomach; hypodermically, by inunction, by inoculation, by inhalation, by injection into the larger blood vessels, and per rectum. (b) Hypodermic doses should be one-quarter smaller, while the rectal dose should usually be one-quarter larger than doses given by the mouth.

3. What are the physiologic effects and medicinal uses of the preparations of belladonna?

ANSWER.—Belladonna is a powerful stimulant and midriatic, contracting the superficial capillaries so as to dry the skin. It is antagonistic to opium.

4. Give the therapeutic uses of the iodides. How are they best administered?

ANSWER.—The iodides are principally used as alteratives, and are well administered dissolved in compound tincture of gentian by gradually increasing doses.

5. What are antipyretics? Describe general use of and how administered.

ANSWER.—(a) Agents used to reduce temperature in disease. (b) They are used when the temperature becomes dangerously high, and are administered in widely different ways.

6. Name the official digestive ferments. Give their physiologic action and therapeutic uses.

ANSWER.—(a) Pepsin and pancreatin. (b) Their actions and uses are to aid gastric and intestinal digestion.

PHYSIOLOGY.

1. Describe the circulation of the blood.

ANSWER.—A complete discussion of this subject would require at least ten or twelve pages, but we will mention here only the cardinal features. The blood circulates through a system of tubes known as the arteries, capillaries, veins. The arteries carry the blood from the heart to all parts of the body and deliver the blood to the capillaries, which in turn distribute it among the tissue cells, and they deliver it to the veins, which bring it back to the right auricle of the heart, from which it passes to the right ventricle, then through the pulmonary artery to the capillaries of the lungs, from which it is collected by the pulmonary veins and brought to the left auricle of the heart, passing next to the left ventricle, then again into the arteries.

2. (a) What is coagulation of the blood? (b) Give some of the theories of coagulation and state how it may be hastened or retarded. (c) What is intravascular clotting? How may it be caused and why does it not take place under ordinary circumstances?

ANSWER.—(a) Solidification or clotting. (b) The best theory perhaps is that coagulation is ultimately caused by disturbance in the lining membrane of the blood vessels, said disturbance liberating a compound which co-operates with the fibrine factors to form fibrine. An exploded theory is that clotting results from exposure to air. Clotting is hastened by agitation of blood and is retarded by moderate heat. (c) Coagulation inside the blood vessels. This may be caused by disturbance of the endothelial lining of the vessel, which lining, however, is usually intact.

3. What is meant by the heat-regulating mechanism of the body? Explain the maintenance of a constant body temperature.

ANSWER.—(a) This part of the question explains itself. A heat-regulating mechanism means a mechanism to regulate heat. (b) The maintenance of a constant bodily temperature is due to the balance existing between the heat-producing forces, such as oxidation of the tissues, the heat-reducing forces, such as the contact of the body with the atmospheric air. The circulation of the blood serves to distribute a uniform temperature throughout most parts of the body.

4. Describe the physiologic functions of the kidneys.

ANSWER.—Function of the kidney is to eliminate such waste products as urea, uric acid, inorganic salts, and water.

5. Describe the mechanism of respiration, both normal and forced.

ANSWER.—Respiration includes inspiration and expiration. Inspiratory mechanism consists in the descent of the diaphram, the elevation of the sternum principally by the scaleni, and the eversion of the ribs by the external intercostals, pectoral and other muscles. Expiration, on the contrary, is purely passive, consisting in the ascent of the diaphragm and collapse of the chest, said collapse being due to the elasticity of the tissues involved. (b) Forced respiration brings violently into play the abdominal muscles during expiration.

6. Describe the phenomena and give some theories of sleep.

ANSWER.—Sleep is a normal and temporary subsidence of all the voluntary functions of consciousness. Theories of sleep are (1) Fatigue of the vaso-motor placentas, (2) Formation of soporific substances during waking hours, etc.—*State Board Journal of America.*

Inclosed find one dollar for subscription to the BRIEF. I would not like to be without the BRIEF, with its bright and instructive articles. I am quite an old member of the BRIEF family, and do not wish to part company with it until the sands of time have run their course.—A. ALLEN NOXON, M. D., Toronto, Canada.

Book Notices.

DISEASES OF THE STOMACH AND INTESTINES. With an Account of Their Relations to Other Diseases and of the Most Recent Methods Applicable to the Diagnosis and Treatment of Them in General; Also, "The Gastro-Intestinal Clinic," in which all such diseases are separately considered. By Boardman Reed, M. D., Member of the American Medical Association, American Climatological Association, American Academy of Medicine, American Electrotherapeutical Association, etc. Illustrated. Second edition. New York: E. B. Treat & Company. Price, $5.00.

These lectures to general practitioners first appeared in 1904, and after a large edition was disposed of it was but natural that an urgent request was made for a new edition. All the important advances and improvements that were found necessary have been made, and much new material has been added to eighteen of the lectures, thus making valuable additions that will greatly enhance the value of this volume.

THE PRACTICE OF OBSTETRICS. Designed for the Use of Students and Practitioners of Medicine. By J. Clifton Edgar, Professor of Obstetrics and Clinical Midwifery in the Cornwell University Medical College; Visiting Obstetrician to the Emergency Hospital of Bellevue Hospital, New York City; Surgeon to the Manhattan Maternity and Dispensary; Consulting Obstetrician to the New York Maternity Hospital. Third edition, revised. With twelve hundred and seventy-nine illustrations, including five colored plates and thirty-eight figures printed in colors. Philadelphia: P. Blakiston's Son & Co. Price, $6.00.

The first edition of this work was printed in 1903, the second in 1904, and the third in October, 1906. It is very creditable to an author that three large editions of his best efforts in a work have had such a recognition. We believe it is one of the best works on this subject that has ever been placed on our review table. There is nothing so convincing in a work of this nature as a host of original illustrations to add to the text matter. It is so completely gotten up and the subjects are so fully elucidated and up to the latest ideas on the subjects, that we are fully convinced as to the fact that no other work can take its place. We note with pleasure that all weights and measurements are given in English with the metric equivalents in parenthesis. The whole work shows wisdom in all its parts and fully meets our approval of what such a work should be.

AMERICAN PRACTICE OF SURGERY. A Complete System of the Science and Art of Surgery, by Representative Surgeons of the United States and Canada. Editors: Joseph D. Bryant, M. D., and Albert H. Buck, M. D., of New York City. Complete in eight volumes, profusely illustrated. Volume II. New York: William Wood & Company. Price, extra muslin, $7.00; brown leather, $8.00; morocco, $9.00.

American practice of surgery has so far advanced in science and art that all other nations stand aghast and wonder as to the daring methods that have proven successful. American works on medicine and surgery prove to all nations that they are authoritative on the subject. When such operators as Bryant and Buck issue such a work as "American Practice of Surgery," it is authoritative and beyond dispute. It took years for these American operators to formulate this work, and they only produced it when, after deep thought, they knew they were absolutely convinced that they were right and felt the responsibility was great. Yet this is the result of long deliberation from a purely American standpoint, and no foreign writers have been invited to take any part in the work, thus making it purely American. It embraces much that has never before been published in any work on surgery.

A TREATISE ON SURGERY. By George Ryerson Fowler, M. D., of Brooklyn, New York City, Examiner in Surgery Board of Medical Examiners of the Regents of the University of the State of New York; Emeritus Professor of Surgery in the New York Polyclinic, etc. In two imperial octavo volumes of seven hundred and twenty-five pages each, with eight hundred and eighty-eight text illustrations and four colored plates, all original. Vol. II. Philadelphia and London: W. B. Saunders Co. Price, per set, cloth, $15.00; half morocco, $17.00.

In this volume we find the same excellence of text and handsome and well-executed illustrations that can only be found in this work. We highly commend the set, as exhaustive and up-to-date.

PLASTER OF PARIS AND HOW TO USE IT. By Martin W. Ware, M. D., Adjunct Attending Surgeon, Mount Sinai Hospital; Surgeon to the Good Samaritan Dispensary; Instructor in Surgery, N. Y. Post-Graduate Medical School. New York: Surgery Pub. Co. Price, cloth, $1.00.

This is one of the most useful books ever presented, not only on account of the general demand for the information and instructions upon the subject which this book so explicitly, practically and comprehensively covers, but because this knowledge was not previously available except from such a vast experience as enjoyed by Dr. Ware, or, in part, by reference to many books on allied subjects. It is a vivid narrative, profusely illustrated, of the many uses to which plaster of paris is adaptable in surgery. The whole subject, from the making of the bandage to its use as a support in every form of splint, corset or dressing, is graphically described and illustrated. The use of plaster of paris in dental surgery is also covered.

THE TECHNIC OF OPERATIONS UPON THE INTESTINES AND STOMACH. By Alfred H. Gould, M. D., of Boston. With one hundred and ninety handsome illustrations on plate paper, most of them original and some in colors. Philadelphia and London: W. B. Saunders Company. Price, cloth, $5.00; half morocco, $6.00.

In a work on technic of operations, the illustrative method of doing these operations is of great importance, and we do not know of any better way to make a work of this nature interesting and instructive, as words do not convey the idea as well as a proper and instructive view of the process by which it is done.

A TEXT-BOOK OF OBSTETRICS. By Barton Cooke Hirst, M. D., Professor of Obstetrics in the University of Pennsylvania; Gynecologist to the Howard, the Orthopedic and the Philadelphia Hospitals, etc. Fifth edition, revised and enlarged, with seven hundred and sixty-seven illustrations, forty of them in colors. Philadelphia and London: W. B. Saunders Company. Price, cloth, $5.00; half morocco, $6.00.

We find in the preface of this edition the following: "The author has carefully revised this edition, paying particular attention to the recent advances in our information regarding puerperal infection and gestational toxemia, but incorporating in the next only the facts that seem at present clearly established. As in former editions, the author has endeavored to keep in mind the needs of the medical student and practitioner of medicine, who must be prepared to accept the responsibility involved in obstetrical practice."

A PRACTICAL TREATISE ON MATERIA MEDICA AND THERAPEUTICS, with Especial Reference to the Clinical Application of Drugs. By John V. Shoemaker, M. D., LL.D., Professor of Materia Medica, Pharmacology, Therapeutics, and Clinical Professor of Diseases of the Skin in the Medico-Chirurgical College of Philadelphia; Physician to the Medico-Chirurgical Hospital; Member of the American Medical Association and the British Medical Association; Fellow of the Medical Society of London, etc., etc. Sixth edition, thoroughly revised. (In conformity with latest revised U. S. Pharmacopœia, 1905.) Philadelphia: F. A. Davis Co., Publishers. Price, cloth, $5.00; sheep, $6.00.

The editions of this work are very large, and should be a great inducement to secure the sixth edition of such a popular work, as many additions have been added to this one, owing to the changes that made it obligatory to change in conformity to the late revised Pharmacopœia. All the original features have been retained, but it was found necessary to make many changes to conform to existing conditions, as throughout all these editions the student and practitioner will find his needs fully looked after.

PARAFFIN IN SURGERY. A Critical and Clinical Study. By William H. Luckett, B. S., M. D., Attending Surgeon Harlem Hospital; Surgeon Mount Sinai Hospital Dispensary. And Frank I. Horn, M. D., Assistant Surgeon Mount Sinai Hospital Dispensary, New York City. With thirty-eight illustrations. New York: Surgery Publishing Company. Price, $2.00.

The introduction of paraffin in certain troubles, where defects are to be remedied —such as depressions of the nose or face where Nature failed to correctly supply the symmetry—is a consideration that should appeal to all practitioners. How to apply this effect to rectify deformities should be thoroughly studied, and you have here a full discussion and illustrative effect, on which you can base a practical idea of the methods.

A MANUAL OF THE DISEASES OF INFANTS AND CHILDREN. By John Ruhrâh, M. D., Clinical Professor of Diseases of Children in the College of Physicians and Surgeons, Baltimore. Illustrated. Philadelphia and London: W. B. Saunders & Co. Price, flexible leather, $2.00.

The author very aptly says, in the preface: "The average medical student attending the third and fourth sessions has about fifteen different branches with which to familiarize himself. The textbooks treating of these subjects average about one thousand pages each, or a total of fifteen thousand pages. The student is busy all day at the college or in the hospital. In the evening he is expected to review the subjects he has considered during the day, as well as fill in the many gaps in the college curriculum. Small wonder is it that, as the German proverb puts it, "he can not see the wood for the trees." This book is for the medical student in these extremes, and should be thoughtfully considered.

YAHB AND CRETINE; OR, RISING FROM BONDS. By Dr. George B. H. Swayze, Philadelphia, Pa. Published by The C. M. Clark Publishing Co., Boston. Price, $1.50.

This work is an interesting story, showing a natural analysis of the race problem in the United States. It is a story that is treated by the representative characters themselves on historical lines in the imperishable interests of harmony and prosperity between the colored and white population in the United States. You will have to read this story to see whether such conditions can ever become a fact. Dr. Swayze's portrait appeared in the BRIEF in April, 1904, and an article from his versatile pen on "The Arrest of Consumption." How ably he treated this subject will show conclusively that this work is worth the time.

ANATOMICAL TERMINOLOGY, With Special Reference to the B. N. A. By Lewellys F. Barker, M. D., Professor of Medicine Johns Hopkins University, Baltimore (Formerly Professor of Anatomy Rush Medical College, University of Chicago). With vocabularies in Latin and English and illustrations. Philadelphia: P. Blakiston's Son & Co. Price, $1.00.

The Basle Anatomical Nomenclature—popularly referred to as the B. N. A.—is the result of an earnest, concerted effort to systematize and simplify a nomenclature which has grown in haphazard manner, become burdened frequently with multiple designations for one structure, and in general has deteriorated in scientific accuracy and value. The expression (B. N. A.) is a shorthand title for a list of some four thousand five hundred anatomical names accepted at Basle in 1895. It is a good reference book.

CONSERVATIVE GYNECOLOGY AND ELECTRO-THERAPEUTICS. A Practical Treatise on the Diseases of Women and Their Treatment by Electricity. By G. Betton Massey, M. D., Attending Surgeon to the American Oncologic Hospital, Philadelphia; Fellow and ex-President of the American Electro-Therapeutic Association, etc., etc. Fifth carefully revised edition. Illustrated with twelve original full-page chromo-lithographic plates of drawings and paintings, fifteen full-page halftone plates of photographs made from Nature, and one hundred and fifty-seven halftone and photo-engravings in the text. Complete in one royal octavo volume of four hundred and sixty-seven pages. Philadelphia: F. A. Davis Company, Publishers. Price, $4.00.

Conservative methods in gynecology will enlist more friends than the extremists in surgery, and all womankind will be thankful for the physician's efforts along conservative lines. There are times when surgery is the only means, but the physician's efforts should be exhausted before it is resorted to. This work has taken firm hold, as evidenced by the necessity of a fifth edition.

SELF-PROPELLED VEHICLES. A Practical Treatise on the Theory, Construction, Operation, Care and Management of All Forms of Automobiles. By James E. Homans, A. M. With upwards of five hundred illustrations and diagrams, giving the essential details of construction and many important points on the successful operation of the various types of motor carriages driven by steam, gasoline and electricity. New York: Theo. Audel & Co. Price, $2.00.

The dissemination of practical knowledge regarding the mechanism and operation of these self-propelled modes of conveyance is an absolute necessity to those who possess machines, and to those who intend to purchase one. This work should be thoroughly read, so that an understanding can be had as to what is best to do.

DISEASES OF CHILDREN. A Manual for Students and Practitioners. By George M. Tuttle, M. D., Attending Physician to St. Luke's Hospital; Martha Parson's Hospital for Children; Bethesda Foundling Asylum; and Professor of Therapeutics Medical Department of Washington University, St. Louis. This is one of Lea's Series of Pocket Text-Books, edited by Bern B. Gallaudet, M. D. Second edition, revised and enlarged. Illustrated with five plates in colors and monochrome. Philadelphia and New York: Lea Brothers & Co. Price, cloth, $1.50; flexible leather, $2.00.

In treating children the practitioner's task is a hard one, owing to the fact that they can lend no aid to diagnosis save the region affected, and a physician who has not treated in the family is often at a disadvantage. A thorough knowledge of this subject is essential to all general practitioners. A reading of such a work as Tuttle's can only result in good.

A TEXT-BOOK OF DISEASES OF WOMEN. By J. Clarence Webster, B. A., M. D. (Edin.), F. R. C. P. E., F. R. S. E., Professor of Obstetrics and Gynecology in Rush Medical College, in affiliation with the University of Chicago, etc. Three hundred and seventy-two text illustrations and ten colored plates. Philadelphia and London: W. B. Saunders Company. Price, cloth, $7.00; half morocco, $8.00.

No library of a family physician is complete unless some good work on diseases of women is included. It is always best to get a good and thorough work, and thus have at hand all that can be said on the subject. Consider this as one of the best.

A TEXT-BOOK OF PATHOLOGY. By Alfred Stengel, M. D., Professor of Clinical Medicine, University of Pennsylvania; Physician to the Pennsylvania University and the Philadelphia Hospitals. With three hundred and ninety-nine illustrations in the text, many of them in colors, and seven full-page chromo-lithographic plates. Philadelphia and London: W. B. Saunders Co. Price, cloth, $5.00; half morocco, $6.00.

This is the fifth, and thoroughly revised, edition of this work, and certainly is a leader in its line, owing to the reconstruction made in the sections dealing with general pathology and the chapters on inflammation, immunity and animal parasites. All in all, the volume has been largely increased in size and worth, and bids fair to acknowledgments as one of the best on pathology.

ATLAS AND EPITOME OF DISEASES OF THE SKIN. By Dr. Franz Mraček, Professor of Dermatology in the University of Vienna. Authorized Translation from the German. Second edition, revised and enlarged and reset. Edited by Henry W. Stelwagon, M. D., Ph. D., Professor of Dermatology Jefferson Medical College, Philadelphia; Physician to the Department of Skin Diseases Howard Hospital; Dermatologist to the Philadelphia Hospital, etc. With seventy-seven colored plates by the artists, J. Fink and A. Schmitson, and fifty half-tone illustrations. Philadelphia and London: W. B. Saunders & Co. Price, cloth, $4.00.

This is one of the series of Saunders' Medical Hand-Atlases, and is a fine specimen of this series, as about thirty new and original plates appear that are not in the first edition. These illustrations lend great aid in diagnosing diseases—especially of the skin. You can not fail to be interested in such a work.

PULMONARY TUBERCULOSIS. Its Modern and Specialized Treatment. With a brief account of the method of study and treatment at the Henry Phipps Institute of Philadelphia. By Albert Philip Francine, A. M. (Harv.), M. D. (U. of P.), of the Staff of Henry Phipps Institute, Philadelphia; Examining Physician to the White Haven Sanatorium, etc. Illustrated. Philadelphia and London: J. B. Lippincott Co.

The treatment of consumption has agitated the minds of the brightest lights in the profession, and any information that tends to lend aid in its treatment should be sought out and thoroughly digested. Will we ever arrive at an absolute cure for this dread disease?

THE HARVEY LECTURES. Delivered Under the Auspices of The Harvey Society of New York—1905-6. By Prof. Hans Meyer, Prof. Carl von Noorden, Prof. Fredrick G. Novy, Dr. P. A. Levene, Prof. W. H. Park, Prof. Lewellys F. Barker, Prof. Frederic S. Lee, Prof. Lafayette B. Mendel, Prof. T. H. Morgan, Prof. Charles S. Minot, Prof. J. Clarence Webster, Prof. Theobald Smith, Prof. W. H. Howell. Philadelphia and London: J. B. Lippincott Co.

This society was organized during the spring of 1905 through the efforts of Prof. Graham Lusk, and its object is the diffusion of the medical sciences by means of public lectures. This work is a grand illustration of what can be accomplished through such efforts.

Editorial.

Complaints.

We have recently received a number of complaints from correspondents stating that they have failed to obtain satisfactory results from the formulas intended to take the place of well-known ethpharmal preparations. What do these doctors expect? It stands to reason that the manufacturer of a proprietary preparation takes greater pains with his product than the druggist who puts up a prescription designed to act as a substitute. The formulas sent out with pharmacopeia names, and which are expected to be included in the National Formulary, are entirely guess work, and no analysis can accurately determine the process of manufacture of an organic preparation.

We know of one proprietary remedy that owes its value to the fact that it is made from the fresh green plant. In the commercial markets the drug in question can only be bought in the form of the dried root, and a tincture made from the latter is absolutely void of the therapeutic properties of the original ethpharmal preparation. Hence the National Formulary is of no practical value to the physician; what he wants is results.

Is the Doctor a Poor Manager?

This is a question that comes up time and again, but we do not believe it can be proven, because the average physician throughout the length and breadth of the country, especially our patrons, seems to have a bank account, and his check is invariably good. Then why the saying that he is a poor manager. He knows the financial status of his trade, and acts accordingly.

The doctor treats all alike—the poor and the rich—and he should not aim to make his wealthy patients pay his poor debts because they can afford to do so. His wealthy patients demand more, and generally pay accordingly, if they are grateful for the service—the poor pay when they can, if they are grateful. Thus it is the faithful doctor who administers alike to the rich and the poor.

Focal Symptoms Without Stroke.

BY HAMILTON BERNARD LOWRY, A. M., M. D., PH. D.,

Professor of Mental and Nervous Diseases in the Nebraska College of Medicine.
Lincoln, Neb.

Whether it is fact or fancy, we often hear it asserted that when a practitioner happens to have an unusual case he may look for one or more of the same kind to follow in close succession. This is claimed even when the practice may not be extensive.

But a few weeks ago, February 27, 1907, Mr. C., a brakeman on a freight train, aged thirty-four, vigorous, and with good family history, while on duty, as he approached the city, noticed that when he dropped his pocket-knife from his right hand he was unable to pick it up—was unable to grasp it, and soon was unable to move the arm. He next observed that his right foot became "clumsy," and, finally, he was unable to move the foot or leg. All this occurred, he thinks, within twenty or thirty minutes, probably the time was much shorter. The entire right side became disabled. Yet he at no time lost consciousness. On arriving in the city he was removed from the car and taken to his home. An hour afterwards he was able to give a detailed and rational account of his ailment to his family doctor, with whom I saw him the next day. He was then distinctly hemiplegic. The trouble involving the lower right side of his face, as well as the right arm and leg. "My tongue is thick, but I think I can make you understand," he said, and proceeded to give me an admirable account of his seizure. He is quite sure that he at no time lost consciousness, but watched himself, without emotion or alarm, become paralyzed on the right side.

To-day, April 1, he showed no improvement, except in his speech, which is less inarticulate than it was when I first saw him. There is no heart lesion and no atheroma, so, apparently, his trouble is due to hemorrhage. This is an ideal clinical picture of "Focal Symptoms with Stroke."

Case 2.—Last night I was called by Dr. S. to see Mrs. H., aged fifty, rather stout, but strong and active, being a professional nurse. A few hours previous to my visit she had sustained a second cerebral hemorrhage, and showed a typical and profound case of apoplexy—"focal symptoms with stroke." But four days prior to this she had complained to her family of *pain*, and a strange feeling in the right side of her head and face. Upon looking in a mirror she noticed that her face was flabby, and her mouth was drawn to the left side. Immediately there were "pins and needles" in her right arm, and her right leg followed by numbness and *loss* of power. Her tongue grew "thick," but of this she made a joke, saying "there *is* nothing to be alarmed at, for nothing can stop a woman's tongue." She never lost the power of speech and never became unconscious. This condition of things lasted for four days, that is, "focal symptoms without stroke" continued until the second attack, when stroke was added *to* the other symptoms.

The psychological aspect of both of these cases is interesting. Each saw voluntary motion go out of the right side of the body. Each actually watched half of his own person become paralyzed, but, strange to say, there was no emotion, no mental worry, no apprehension, and yet the nurse in her normal condition undoubtedly would have known the significance of such symptoms.

115 North Eleventh Street.

Correction.

In my "Practical Notes," in the May issue, the printer has made some errors which I beg you to correct: The prescription on page 378 had been written by me purposely, without abbreviation, ℞. Lithii iodati (not Iodati) 1.50. Pulveris (not pulv), quantum satis ut fiant pillulæ I did not write M. Et fiant; this would not be right; besides Et, with a capital E, looks like Bridget's letter, "I love you." On page 379 the printer has reversed completely what I wished to convey, for he gives "we have not to write fiat pillula." In fact, this is exactly what we have to write: fiat pillula and fiant pillulæ.

A. ROSE.

[Written for the MEDICAL BRIEF.]

The Evolution of Insanity.

BY ROBERT JONES, M. D., M. R. C. P., F. R. C. S.,

Resident Physician and Superintendent of the London County Asylum, Claybury; President of the Medico-Psychological Association of Great Britain and Ireland.
London, England.

NO. I.

The earliest times of which we have any knowledge of insanity long preceded the Christian era, and it is fairly certain that mental affections were recognized and treated by the Egyptian priesthood at least 2000 B. C., but happily they were treated as individuals suffering from disease, the mental remedial agents being not only music and the beautiful in nature and art, but bodily recreation and occupation as well.

In biblical history we have the record of well-marked dangerous, if not homicidal insanity, in the conduct of King Saul being treated with persuasive tact and music; then we have King David feigning madness in Gath (1 Sam., xxi, 13-14), for he "scrabbled on the doors of the gate, and let his spittle fall down upon his beard," but he was treated on account of his supposed affliction with fraternal care by the Philistines, who were his avowed enemies. We have also Nebuchadnezzar suffering from definite insanity, and we are compelled to believe that the treatment was humane, for, after seven years of madness he recovered, and was replaced upon the throne of Babylon.

The period succeeding the Hebrew history finds civilization, with its penalties, also advancing westward. The priests, as a special caste with special privileges, by now had lost much of their influence, which implied that a still more humane and intelligent treatment had commenced.

The "humoral pathology" of Hippocrates, which connected mental states with altered conditions of the blood, lymph and bile—thus anticipating the sanguineous, lymphatic, bilious, choleric and other temperamental states of later times—suggested treatment by bleeding, counter-irritants, purging, emetics and baths; and it is of peculiar interest at the present moment, when we ourselves are suggesting a fresh nomenclature, to note that during the time of Hippocrates, Galen and Aristotle, the period of Greek pre-eminence, an attempt was first made at a classification of the insanities. Corresponding in time to a later period of Greek influence, the gospel narrative of the author of the Christian religion affords us lessons of the most extensive humanity in the treatment of mental affliction, and the example and teaching therein recorded are possibly responsible for an account, which may be authentic, of the treatment of mental disorders in Jerusalem about the fifth century. With the decline of Greek influence, about the third century of the Christian era, anoth-

er reaction seems to have set in. Ignorance and superstition again prevailed, and not until the rise of the Bologna school in the seventeenth and eighteenth centuries, with experiments upon animals, was further progress made.

Knowledge of nature has always coincided with the decay of superstition; and with this decay incantations, spells, sorcery and witchcraft also die, for they are only pretended powers claiming to vary natural phenomena. In superstitious times the conscience of man looked upon the world as governed by some good or evil agency, sometimes both; and through the tendency to regard unknown or imperfectly known causes and effects from an anthropomorphic standpoint, cosmic phenomena tended to be personified. This simple appreciation, viz.: The possession of man by a spirit—in the case of epilepsy it was both good and bad (*morbus sacer seu demoniacus*)—afforded the indication for treatment. The evil spirit either had to be propitiated to avoid harm, or it had to be expelled with some magic charm or by means of a mystic ceremony, which latter implied an active religious rite by the priest, accompanied by sacrifices and occult incantations, and a more or less heroic ordeal for the patient, accompanied by oblations, purifications, and frequently by tortures.

The whole of the Middle Ages witnessed the association of demoniacal possession, of exorcism, and of witchcraft, and only with the laws passed against witchcraft in 1736 were these abated. This was a period of epidemics of plague, famine and pestilence, and during this period over one hundred thousand persons are stated to have been put to death for witchcraft and sorcery, of whom about one-third were lunatics.

The notion that insanity was caused by demoniacal possession was long retained, and the help of the church was naturally invoked to exercise the evil spirits. Incantations, mystical rites, the use of salt —the emblem of immortality—holy water, and the offering up of masses, all figured in the early cure of mental diseases, as they still do in the East, and as the recent report of the medical superintendent of the new Syrian Asylum in Beyrout testifies.

It is interesting to note that the first custodial institution for the care of the insane was founded in Florence in 1389; then shortly afterwards, in 1403, one was established in England by the use of "Bethlem," subsequently in 1660 the Hôtel Dieu, in Paris, was opened, and in 1737 an institution was established in Pennsylvania.

The revival of general knowledge of science, art and of literature, gave encouragement to the so-called "somatic" school. Insanity was now regarded as a condition of physical origin, and the decline in cures by faith, hope and forgiveness at once became apparent. To this school we are indebted for the spirit of research which characterizes our own day.

It is interesting to investigate the earliest reliable accounts of the care of the insane. They come to us from the Saxon times, and reveal a curious medical treatment—a compound of pharmacy or polypharmacy with superstition and castigation. The most grotesque and often the most offensive substances entered into the remedial list, and their administration was not infrequently accompanied by severe rites or ceremonies to be observed by the patient. Of the plants in use—and the herbal treatment of Dioscorides and Apuleius was repeated in later days—the peony was considered a special remedy for the cure of insanity. The mugwort, a composite plant, was especially favored for the cure of a mental illness arising through a demon. The periwinkle was also prescribed for demoniacal possession, but to be effective it was to be picked when the moon was nine nights old. The dandelion—called in Wales the "devil's eye"—was definitely associated as a cure for this "devil's sickness." Some of the Ranunculaceæ, noted for their acridity, were especially popular, and the mandrake took a high place as a cure for witlessness. Henbane was then used as a reliable remedy, but with instructions emphasized that the essence should be drunk out of a church bell, and simultaneously with the singing of seven masses by the monks. Burton, in his Anatomy of Melancholy, written in 1621, suggests that herbs should be used for the cure of madness; particularly should borage be used for the heart, poppies for the head, and

wormwood for the stomach. Plants were often placed under the pillow and slept upon, and the practice of outward application by salves was also in vogue, but as a necessary condition in the use of outward application. Masses were compulsory. Holy water had to be used, the sign of the cross had to be made, and incense burnt. The early physicians very thoughtfully, if not somewhat astutely, allowed some considerable time to elapse between the patient's first and second visit, as their prescriptions were not always easy of execution, and in the meantime the *vis medicatrix naturæ* had time to effect a cure which was ascribed to the remedy. The treatment of insanity at holy wells is another method accredited to romantic superstition. The wells of St. Winifred in Wales, of St. Maree in Ross-shire, Great Nun's Pool, St. Fillans in Perthshire and St. Ronan's near Butt of Lewis, are well known as resorts for mental invalids, and who can say that this treatment was not the anticipation of the "long immersion" of today?

Hack Tuke states that the first literary reference to insane persons in Great Britain is made by Gerald, the Welshman, who states that medicine could only be obtained in the monasteries, as the monks were the only practitioners; also that those persons were lunatics whose attacks were exacerbated when the moon every month was at the full. The "Vision Concerning Pier's Plowman," written by William Langlande in the fourteenth century, calls lunatics "God's minstrels," but from that time until the eighteenth century the history of the treatment of the insane is one of harshness and cruelty, alternating with torture, persecution, superstition and ignorance.

The two centuries following the death of Shakspeare who makes frequent reference to insanity, witnessed the treatment of the insane by flagellation, torture, confinement in dark rooms, and acute suffering, often until death relieved them. It was a treatment of the greatest cruelty, inhumanity and barbarity. The insane were tied to crosses, to pillars in churches; flogged at "trees of truth," or burnt as sorcerers at the stake.

The milder forms of mental disorder were treated by pilgrimages to the shrines of certain saints who were reputed to have particular skill and success in the exorcism of evil spirits, and if they were not cared for at the shrines they wandered homeless about the country. Lunatics from all over Europe were brought to the shrine of St. Dymphna, in Belgium, for miraculous healing. Those who were a menace to the community were either chained in dungeons or sent to the common prisons, and this as late as the beginning of the nineteenth century.

Up to the fifteenth century the weak-minded and the insane were associated with criminals and other dependent persons (those whom we now term paupers), who, at that time, were under one authority. Gradually, however, owing to the accumulation of lunatics in prisons a distinction was drawn between these and criminals, and the two classes were separated; the insane being taken to cloisters and monasteries, as is exemplified today in the use by the mentally afflicted of the priory for the brethren and sisters of the Order of the Star of Bethlehem. The engravings of the great pictorial satirist, Hogarth, and the records of Evelyn, show to what barbarity and cruelty the insane were subjected—fastened in chains, strapped in covered cribs, confined in wristlets and strait-jackets, even as late as the year 1841. This wretched torture, the neglect and the horrible injustice shown to the insane, are vividly described in the *Gentleman's Magazine* for July, 1804, in a letter to Dr. J. C. Lettsom, part of which is as follows: "I was shown downstairs into a room (Launceston Workhouse) in a very dirty state, in which a poor lunatic was confined. He lay stretched on a little short and dirty straw, with a few rags on him. His fixed, intent eyes; his shaggy hair, long beard, dirty and livid face, gave him the appearance of a monster. The floor of the room was earth, and literally a puddle of water and dirt more than an inch deep. The keeper had unmercifully beaten the poor fellow, and given him two black eyes."

The harsh measures of the eighteenth and early nineteenth centuries included also crude, severe and unsympathetic medical treatment, *e. g.*, blood-letting in the standing, recumbent, or sitting posture; active counter-irritants, drastic purga-

tives, the shower-bath, emetics and heroic doses of tartarized antimony, of mercury and of digitalis. These have now given way to hygienic measures, exercise and suitable medicinal and moral treatment, of which congenial occupation and amusement form especial features.

Although the nineteenth century has been described as the "most conceited since God made man," it is entitled to be recorded as the most illumined period in regard to the rational, humane and scientific care of the insane. It is only during this period that the metamorphosis—if it may be termed—of asylums has taken place, and if we correctly appreciate the spirit of the times there is a growing tendency to further metamorphosis, *i. e.*, to a greater sub-division and specialization for the great class of defective and morally infirm section of the population. As a contrast to the jails, shrines, holy wells, chains, tortures and exorcism, we have today suggestions for the care and cure of early cases of insanity by "reception houses," and we already have well-planned and furnished hospitals for the acutely insane, others for the chronic insane; asylums for the criminally insane, institutions for the inebriate or chronic drunkard and for the feeble-minded, and finally we have colonies for the epileptic. Probably in the immediate future we shall have penal or educational settlements for the idle or "work-shy," and suitable colonies for the care of the profligate, the vagrant, the prodigal and the facile.

As one of the most brilliant examples of lunacy reform, there exists in London today an institution which has survived the vicissitudes of criticism. From being the "Bedlam" of reproach, the Bethlem Royal Hospital has now become the most enlightened hospital in the world for the treatment of mental diseases.

We owe to Pinel, whose work was translated into English by Davis, of Sheffield, a philosopher, scholar and physician, and to his successor, Esquirol (the Hippocrates of psychological medicine, as he is called), to Griesinger, to Guislain, and to many others, the deepest obligations for more exact knowledge and information in regard to the treatment of the insane, and for the abandonment of cruelty, barbarity and inhumanity. Sainthood is not the exclusive property of the church, and those of us who practice in the department of psychological medicine have also our calendar. The names of Conolly, Tuke, Gardiner, Hill and Charlesworth are pre-eminently those of apostles and saints in regard to the more humane treatment now universal in asylums for the insane.

The history of this improvement has coincided in the main with the history of special legislation, a statement which emphasizes the necessity for further legal changes, as we in England are not at present permitted by law to treat insanity, even in the earliest stages, as other bodily diseases are treated, viz., in special homes under the care of special trained and skilled nurses, obviating the necessity of placing them under certificate of insanity, a course at present compulsory. Previous to 1828 there were but few legal enactments dealing with the care of the insane, those existing at this time dating back only to the second or third year of the reign of William IV, although the Lunacy Commissioners inform us that statistics may be traced as far back as the reign of Edward II. Prior to 1828 the Royal College of Physicians, represented by five of its fellows, had the supervision and licensing of asylums in London and Westminster within a radius of seven miles, whilst the county justices of Middlesex and other counties acted for the provinces, a supervision which was not to the advantage of the insane. In the year referred to the number was augmented to fifteen Fellows of the College, and in 1832 this body was styled the Metropolitan Commissioners in Lunacy. In 1845 the board of eleven Commissioners in Lunacy—now only eight—was appointed; of the latter two are honorary and six are paid, and it is since this systematic visitation of all institutions for the insane, and since the control of nearly all lunacy procedure has fallen into the hands of these Government officials, that the care of the insane has become the proudest boast as to progress in the nineteenth century. So complete is the authority the Lunacy Commissioners exercise over the certified insane that there are few circumstances in connection with persons of unsound mind which do not fall under their immediate control.

It is impossible to estimate correctly the number of insane persons at the beginning of the nineteenth century, as not until January 1, 1859, was the number of lunatics officially registered. At that date there were 36,762 insane persons, a proportion of one to every 536 of the population. The number of registered insane persons in England and Wales when the Lunacy Commissioners were first appointed was 11,272, there being then only fifteen county asylums. Now there are 121,979, and a total of 176 hospitals, licensed houses and asylums.

This record would not be complete without allusion to the more recent legislation for the idiot and imbecile. Up to 1847 no separate provision existed for this class, but Dr. Andrew Reed, a philanthropic divine, began to interest himself in this class, and subsequently founded the Earlswood Asylum, from which, as a pioneer, sprang several other most deserving and useful charities.

In 1886 an act was passed permitting backward children to be placed in such institutions upon one medical certificate merely stating that such a course would benefit the child, so that it is now no longer necessary to certify these backward children as "lunatics." We have further, for children less afflicted, the "Epileptics and Defective Children's Act" of 1899, making it permissible for public authorities to provide suitable educational facilities for this class.

Many of the vagrants, "ne'er do weels," profligates and immoral persons; criminals and lunatics, are recruited from these classes; and in my own experience cases are received into asylums from prisons who, in infancy, have attended hospitals and charities as mentally and physically defective. If the stock is to be kept free from taint a proper supervision should be kept over this class. In country districts they are more definitely known, and a certain amount of "communal vigilance" is exercised over them, but in towns this is obviously impossible, and it should become the duty of the State so to register them by special notification through the schools as to direct and control their lives, and to see that adequate care is exercised over their destinies in specially adapted schools, homes, colonies or settlements. Such a regard would tend to lessen the necessity for increased asylum accommodation.

What have been the contributory factors to the changes in the treatment of the insane, and what do they signify? The answer to the former question is found in the undisputed fact that mental diseases form an integral part of disorders of the nervous system, and are not a fragment detached, as it were, from the domain of general medicine. Possibly also the mental infirmity of King George III gave an impetus to the more enlightened treatment of mental diseases, which even long after this period continued to be a reproach.

The fact that all institutions for the care of the insane are carefully inspected by Government officials of recognized professional ability and rank in law and medicine, whose reports are made public, has had a great effect upon the care of the insane, also the fact that they are, for the most part, supervised by unsalaried boards of trustees representing charities or managers and visitors elected by the people; and I think we may legitimately claim the further fact that institutions for the insane are served by responsible medical authorities, who link their reputations with those of the institutions they serve, and to which they devote their time with loyal energy and fervor.

There is in consequence of the above reasons more confidence on the part of the public, which induces them to send into these institutions all mentally infirm persons from whatever cause; more especially do we now find old people admitted who are suffering from the decay of nature, and whose friends no longer have the necessary time, the accommodation, nor the means to supervise them; cases which, in the circumstances of the past, would have been retained by their relations in their own homes. Upon this point going back to 1859, we find that fifty-six per cent of all pauper lunatics were in asylums, the rest being in the work-houses or with their friends. In 1905 over seventy-eight per cent were in asylums, showing among other causes, that probably the capitation grant of 1874 may have had the effect of sending into asylums a large number of chronic and

incurable patients formerly detained in work-houses and kindred institutions. Most of these cases, in spite of their transference in a state of senility and infirmity, owing to their improved sanitary surroundings, live longer, and, therefore, tend to accumulate in our asylums. Added to these senile cases there is an increasing number of young people who, being mentally defective (and this defect is now recognized by law), are, whilst children, looked after and cared for at home and in special schools, but as adolescence approaches and they begin to give trouble, they are brought into our asylums. Most of these cases, owing to the very nature of their affliction, are incurable from the start, and they help to form the chronic remainder of hopeless cases. This burden of the incurable insane is growing fast and fresh, so that accommodation is constantly being called for.

This defective community—defective in intelligence, defective in citizenship, and in productiveness to the common weal—has become a burden which must needs cause apprehension, and can not but keep awake public interest in the great question of social pathology. To some extent the press, which is occasionally a "potent and practical philanthropist," has been the proximate cause of official investigations into the data of this great subject. An article in the *Contemporary Review* of April, 1903, was the origin of the Inter-Departmental Committee on Physical Deterioration, some of whose recommendations are at present under consideration, and there have also been other committees or commissions, one on the vagrancy question, one on the feeding of children, another on the feeble-minded, and yet a fourth into the working of the poor law.

As Sir James Crichton-Browne eloquently remarks: "Unfortunately lunacy is a bye-path in public affairs hidden from the busy thoroughfare, a bye-path so somber and melancholy that most men are anxious to avoid it. Even when our men of light and leading realize in their own family circles, as they sometimes do, what madness means, they are averse to touch in public upon any question associated with their own grievous private calamity, to which a sense of reproach in some degree attaches."

[Written for the MEDICAL BRIEF.]

Brass-Workers' Disease.

BY S. HERBERT PERRY, M. D. (LOND.), M. B., B. CH. (BIRM.),

Late Assistant Physician to the General Hospital, Birmingham, and Physician for Out-Patients to the Children's Hospital. Birmingham, England.

Brass-working constitutes a large and important section of the industries of Birmingham, and for that reason there is little need to apologize for bringing the subject forward. Moreover, much of the most important medical work on the subject has been performed by physicians of this city.

It will be well to review briefly the processes of brass-founding. The first process consists of the melting down of copper and spelter (*i. e.*, crude zinc), together with, possibly, varying quantities of lead, tin and brass dust. It should be remembered that small amounts of arsenic or antimony are commen impurities of commercial zinc. During this process the zinc deflagrates, and a white cloud of zinc-oxide is given off. It is this process, together with the pouring of the molten metal into the moulds, which causes the so-called brass-founders ague. During the pouring of the metal, the deflagration continues, and the fumes are distinctly irritating. Following on are the processes of dipping, filing, polishing, etc. In my experience the polishers are very apt to suffer from anemia and gastro-intestinal trouble, such as gastritis, nausea, a metallic taste, and constipation or diarrhea. For the dipping, a strong solution of aqua fortis, often containing arsenious acid, is used. The fumes from this solution are irritating, and the dippers have a tendency to subacute and chronic bronchitis. The processes of turning, filing and finishing have their special dangers, owing to the constant presence of brass dust in the atmosphere of the shops. Lacquering and bronzing have also dangers of their own. In bronzing a powder commonly used is a copper precipitate with which arsenic may be mixed, and in making black and green bronze the articles are immersed in acid with sal-ammoniac, or with arsenic and sulphur.

I wish to draw attention to the frequent use of arsenic in these processes. I have not attempted any elaborate technical details, but have endeavored to show the dangers in which the workers are involved, and to point out that zinc and copper are not the only metals to which the workers are exposed. It will be obvious that much of the danger to health could be prevented or lessened by efficient ventilation of the workshops. This is carried out by the large firms, but I find that the majority of my hospital patients, who have symptoms of brass-poisoning, come from small firms where the ventilation leaves much to be desired.

Among the symptoms of chronic brass-poisoning there are none that are actually pathognomonic; and on these grounds I have heard the view expressed that a large proportion of these diseased workers do not suffer from copper-poisoning at all, their condition being merely due to the coincidence of certain symptoms with the saturation of their body tissues with copper compounds. That this saturation occurs there is no manner of doubt, in view of the tooth discoloration usually seen, and the occasional greenish hair and sweat of the older workers. The fact that the older workers are less affected than the younger is no proof of the harmlessness of the metal. There is good evidence to the effect that arsenic can be, with long practice, taken in considerable quantity; possibly it is so with copper. My experience is that it is usually the young workpeople who are most easily affected by brass-poisoning, and that the girls employed in the polishing and press shops suffer most of all. It is impossible to definitely say to what extent these younger women are affected, owing to the fact that anemia, which appears to be a prominent early sign of copper-poisoning, is so common an ailment of young female workers.

It is certainly common to find the older workmen with a deep green tooth-line, and possibly hair of a greenish tint, yet having no symptoms of any definite ill-health. I say definite ill-health because comparatively few of the factory hands of this city present a really healthy aspect, and we must always guard against the assumption that anemia, gastritis and constipation are due to copper-poisoning, because the patient has a green tooth-line. One of the largest brass-founders of this city expressed to me the opinion that the symptoms of brass-poisoning, acute and chronic, were more likely to appear in alcoholic subjects than in temperate men. This may be so as regards the acute attack, but the marked occurrence of chronic symptoms in young girls seems to negative this alcoholic theory. This manufacturer also stated that in an epidemic of lead-poisoning which affected his works some years ago, the alcoholic subjects were chiefly and most severely affected. This statement is of interest in view of the recent evidence to the effect that small amounts of arsenic are unusually poisonous when absorbed by alcoholic subjects. I have noted cases of lead-poisoning among brass-workers (as lead is used in making some forms of brass), but have not noted any relationship to alcoholism.

With regard to the frequency of anemia among brass-polishers, it seems reasonable to suppose that copper compounds act as toxins in the human system, and that the young workers are more susceptible than the older ones; just as childhood is susceptible to a variety of special conditions owing to the want of immunity, and just as the toxemia of the constipation of young women is apt to be associated with an anemia which does not occur among older women, in spite of the prevalence of constipation amongst them. That is to say, speaking generally, the younger organism is more likely to be affected by a toxemia than the older one. There is logical evidence to the effect that copper causes certain chronic poisoning symptoms.

The following are the chief groups of the diseases common to brass- workers:

(1). Anemia, with chronic or subacute gastritis and constipation or diarrhea.

(2). Bronchial affections; subacute tracheitis and bronchitis running on to chronic bronchitis and emphysema or phthisis.

(3). Pulmonary tuberculosis.

(4). Certain nervous diseases.

(5). Chronic renal diseases.

Practically there are two main groups:

(1). The anemic and gastric group.

(2). The pulmonary group.

There are certain neuropathic symptoms of chronic brass-poisoning, but I have no experience of the production of cerebral or spinal-cord degeneration by brass absorption. With reference to chronic nephritis it will be remembered that in brass-founding, lead may be used in sufficient quantity to give rise to plumbism. In speaking of chronic nephritis, I refer to a condition in which both definite albuminuria and casts exist; no doubtful cases are included. So with regard to pulmonary tuberculosis, all doubtful cases are eliminated.

The earliest sign of brass absorption is a green or yellow line upon the bases of the teeth. This line is upon the teeth, not deposited in the tissues of the gums, as is the lead sulphide deposit of plumbism. This green tooth line Professor L. Lewin describes as follows: Almost all who come into contact with pure copper, brass and bronze dust show on the border between the gums and the teeth a dirty green discoloration on the latter, most pronounced on the incisors and canines, and only to a small extent observable on the molars. Almost always the greenish color is situated upon a layer of tartar. It consists of basic carbonate of copper. In those who absorb much copper-dust there is often to be seen a bluish black coating, which sometimes covers the whole tooth, and can, with difficulty, be removed by pumice stone. This, Professor Lewin regards as a sulphide of copper. With regard to the green hair of copper-workers he states that after very prolonged boiling with dilute acetic acid in two out of six specimens, a faint copper reaction was obtained with ferro-cyanide of potassium, and that it is not possible to state definitely whether the color is caused by superficial deposition on the hair, or whether it is in the interior of the hair itself. Professor Lewin states that the frequency of this green hair is not great; in my experience it is fairly common, but only among the older workers. At a stage earlier than that of the green tooth discoloration, a yellowish line may usually be noticed; this consists of minute particles of brass or copper dust. The stages of tooth discoloration are, therefore, presumably brass dust, basic carbonate of copper, and finally sulphide of copper. The origin of this pigmentation is doubtless the brass or copper dust inhaled, this inhalation accounting for the fact that the pigmentation is usually limited to the incisor and canine teeth.

The Anemic and Gastric Group of Cases.—With regard to this group one has always to bear in mind that there are no actually definite symptoms by which an anemic condition can be assigned to brass or copper. However, if a young woman presents herself with a definite history of the onset of anemia and dyspepsia within six months or a year of commencing brass-work, and if the teeth show the typical coloring, it is reasonable to regard the case as one of the chronic brass-poisoning, provided that there is evidence that the anemic condition did not exist prior to the undertaking of brass-work. My analysis shows that such cases occur with considerable frequency among young females and to a less extent among young males.

These cases of anemia are apt to run on into pulmonary tuberculosis; the debility lowers the resistance to tubercle.

A variety of nervous conditions have been noted in brass-workers, but probably few of these have any definite relation to the metals employed. Different authors have described:

(1). Various forms of tremor.
(2). Paralysis agitans.
(3). Locomotor ataxia.
(4). Peripheral neuritis.
(5). Progressive muscular atrophy.
(6). A certain form of paraplegia.

I have seen two definite cases of tremor of the hands, lips and tongue occurring in women. Both patients showed a marked green tooth-line, and in both cases the condition was apparently caused by the use of a brass blow-pipe. Furnishing the blow-pipe with a mouth-piece of tin brought about a cure in both cases. The tremor was fine in quality, not unlike that of general paralysis, and in addition the reflexes were generally increased; there were no other signs of neuritis or cord degeneration. The patients' ages were thirty-two and thirty-eight.

The other nervous conditions were chorea, locomotor ataxia, melancholia and hiccough of a week's duration. I have no reason to believe that these conditions

had any etiological relation to brass-working, except that the hiccough might be set up by a gastric condition. There was, however, no obtainable syphilitic history in the case of locomotor ataxia. More recently I have seen a case of primary double optic atrophy occurring without known cause in a male brass-worker aged forty-five years.

Tremor has been noted in chronic brass-poisoning, but though paralysis agitans has been stated to be not infrequent, I have not seen a definite case of this disease. After tremor it would seem that peripheral neuritis is most likely to occur. In this connection it should be remembered that zinc spelter contains an appreciable amount of arsenic.

There is reasonable evidence to the effect that copper may give rise to signs of a chronic poisoning more especially in young adults. The fact that gold-workers also suffer is valuable confirmatory evidence. That copper miners develop a tolerance of the metal agrees with my analysis of cases; those brass-workers affected being largely the younger workers, and chiefly females. The older men, in my cases, suffered chiefly from pulmonary or renal disease.

Professor Lewin's opinion, however, is strongly opposed to a toxic copper theory. He considers that of the numerous copper and brass-workers whom he has seen, questioned and examined, and who had absolutely no reasons for concealing any illnesses which might be the result of their work, there was not one who had suffered from chronic copper-poisoning; not one who showed symptoms of ill-health, either of a temporary or permanent character, which could make him regard the person as diseased. He finally concludes that if a copper-worker shows injury to health it is scientifically more correct to attribute it to other injurious metals used, to the hardness of much of the work, to its long duration or to bad sanitary conditions, than to the copper itself.

We may now briefly consider the acute form of brass-poisoning and its causation. This—the so-called ague—attacks the mixers and moulders, not the dippers, finishers and polishers. The evidence of the workmen is definite as to the fact that these attacks occur only among those exposed to the fumes of the molten metal of which spelter (crude zinc) forms a part. Dr. Arlidge states that "similar symptoms (ague), occur among brass-workers where no zinc vapor is thrown off," but my experiences do not bear this out. The workmen have assured me that if they are copper-smelting only, they are not exposed to the acute attack. There is evidence also that such attacks do not occur among the copper smelters of the mining districts. One of the striking symptoms of chronic brass-poisoning in young adults is the occurrence of profuse sweats.

The attack of so-called ague has been variously described. The description given by Dr. Simon is exact, and with it my investigations agree. The statement that only young or fresh workers are attacked is not quite correct. It is not easy to establish tolerance; only recently a workman (a moulder), informed me that though in the trade for many years, he was always definitely attacked after a few days' holiday, and that even the Sunday holiday often caused him some malaise on Monday evening. The attack, almost always comes on at the close of the week in the evening. During the inhalation of the fumes, there is apt to be a sense of burning and heat about the pharynx, esophagus and stomach; in a young worker this may run on to vomiting about two hours afterwards, this pointing to the ingestion of some irritant poison. In the older workers this rarely occurs, the attack coming on during the evening. The attack consists of shivering (not a definite rigor), with nausea and a considerable sense of malaise. There may be some sweating, but not, I think, much more than the nausea and vomiting with their attendant depression would account for.

Both Dr. Greenhow and Dr. Hogben state that after the rigor and vomiting there follows a hot stage with slight febrile reaction, and subsequently profuse sweating. I can not find evidence of these stages, or of any febrile reaction. Dr. Hogben writes of this so-called ague that it may frequently be seen in the out-patient rooms of our hospitals; as a matter of my own experience it is very rarely seen, if ever. The men accept the attack

as a natural consequence of their employment, and take small notice of it. Some, I believe, treat it by taking milk; most of those with whom I have talked usually treat it with beer and go to bed.

As to the cause of the acute attack: The chief metals used are copper and zinc. Small quantities of lead and tin may be used, and in addition, very small, but recognizable quantities of arsenic or antimony are present in crude zinc, varying according to the quality of the zinc.

Professor Turner (Professor of Metallurgy in the University of Birmingham), informs me that commercial zinc (spelter), varies in its composition, and that the amount of arsenic or antimony might vary considerably; it would, in any case, be very small. Commercial zinc has, it appears, much improved in purity during recent years. There is good reason to suppose that copper fumes do not cause these acute attacks. When the metal is molten, pale greenish flames rise from it, and the zinc deflagrates, giving off white clouds of zinc-oxide. There does not seem to be reason to suppose that zinc-oxide taken by the mouth would cause irritation. Dr. Hogben points out that such acute symptoms do not occur among other workers exposed to zinc fumes, such as the galvanized iron workers. He also mentions that the exhibition of oxide of zinc by the mouth is not known to produce any results comparable to brass-founders' ague. In order to prove whether the inhalation and ingestion of practically pure zinc (such as is used in laboratories), has any bad effect, I experimented upon myself, and on several occasions thoroughly inhaled the white fumes arising from deflagrating zinc; the zinc being deflagrated in a crucible, small amounts at a time. There was no effect beyond a slight laryngeal irritation, which any other powder might have caused.

There is, then, no definite evidence to the effect that the fumes of deflagrating pure zinc cause the attack. Spelter, however, as I have shown, is impure, and contains among other impurities, small and varying amounts of arsenic. Arsenic is also contained in considerable amount in the crude sulphuric acid used by the brass dippers. In this connection Dr. Oliver writes: "In my own experience zinc-oxide was administered to animals over a very long period, and in considerable doses; but when the drug was perfectly pure none of the rapidly fatal results occurred. Rabbits take it by the mouth for many months without seeming to suffer much discomfort; and in the mixing department of large color works men who breathe the dust do not, as a rule, suffer any inconvenience. It may seem to cause headache, nausea, vomiting and, cramp-like pains in the limbs; but as zinc-oxide is frequently impure, containing small quantities of lead and arsenic, these symptoms are more probably due to the adulteration than to the metallic compound itself."

The symptoms of brass-founders' ague correspond to the ingestion of an irritant; at first a sense of heat in the throat and stomach, and later on nausea, vomiting, sweating and depression. The fact that milk is used as a remedy also suggests arsenic. The amount of arsenic contained in impure zinc is only minute; but arsenic, being highly volatile, would probably be driven off from the molten metal with great rapidity, and in the early stages might be present in the fumes in a noticeable quantity. Antimony, if present, would not be volatilized. The dippers are also exposed to fumes of arsenious acid from the acid fluid used by them; this might account for their tendency to bronchitis.

Treatment.—The work people seem to be generally agreed that the acute form of poisoning is best treated by a draught of milk. This treatment suggests that this acute attack is due to the ingestion of an irritant, and, as I have previously suggested, it is possible that this irritant may be some arsenical compound given off from the molten metal. It is certain that it is only the mixers and moulders (those exposed to the fumes of the molten metal) who suffer from the acute attack; the polishers, finishers, etc., do not experience the so-called brass-founders' ague. There is some doubt as to the most effectual treatment of the symptoms of chronic brass-poisoning. Dr. Simon and others hold that potassium iodide is an effective curative agent, but I can not say that I have had good results from its exhibition. As a rule I have found the best line of

treatment to consist in the usual treatment for anemia (an aperient iron mixture), together with wherever possible the giving up of brass work for a period of time, at all events.

Dr. Murray claims to have found a specific in the shape of phosphorus. He was led to this treatment "on the empirical idea that sulphate of copper, being an antidote for phosphorus poisoning, phosphorus might, in some manner, exercise an antagonistic influence on copper." The objection to this empirical idea rests on the fact that sulphate of copper is only a mechanical antidote to phosphorus, it is reduced by the metalloid, the copper being deposited on the phosphorus (in the stomach), and rendered inert. There does not seem reason to suppose that there would be any such reaction between copper and phosphorus compounds when circulating through the blood and tissues. Dr. Murray recommends for a dose 1/30-grain of phosphorus, or fifteen minims of the dilute phosphoric acid. I have tried this treatment with no result beyond that which I should expect from the valuable tonic properties of phosphorus. In my opinion cessation from brass or copper work, together with suitable symptomatic treatment (for anemia, phthisis, bronchitis, etc.), constitutes the most valuable treatment.

The notification of brass-poisoning has recently been suggested, and I believe one or two cases of death have been certified as due to chronic brass- or copper-poisoning. In my opinion the notification of brass-poisoning must be considered as quite impracticable. As there are no definitely pathognomonic signs or symptoms of chronic brass-poisoning, and it remains to be proved that the acute attack is due to zinc or copper. Patients do not die actually of brass-poisoning, but from its long-continued results. Pulmonary tuberculosis is prevalent among brass-workers, but it would be illogical to notify a case of phthisis as one of chronic brass-poisoning, since the brass is probably only one of the etiological factors. The absence of pathognomonic symptoms renders notification impossible. It is to be remembered that every patient with a green tooth-line is not suffering from chronic brass- or copper-poisoning, just as a blue gum-line does not necessarily imply chronic lead-poisoning.

Prevention may be summed up in a few words; it must consist in efficient ventilation, including efficient extraction of the brass-laden air, combined with the personal cleanliness of those who handle brass or copper, and the use of some form of mouth and nose protection by the mixers and moulders.

[Written for the MEDICAL BRIEF.]

Neuralgia and Its Treatment.

BY VINCENT F. LENNANE, L. R. C. P., L. R. C. S. (EDIN.); L. F. P. S. AND L. M. (GLAS.).
Late Colonial Surgeon, Gold Coast.
London, England.

There are few more painful diseases than neuralgia, and there is certainly none which gives rise to such dire suffering. By some it is said to be merely a symptom, and not a distinct morbid entity, but this is a source of but little consolation to those whose days are made miserable, and whose nights are rendered sleepless by its unwelcome presence. Undoubtedly many cases of the so-called neuralgias are due to gross organic lesions, such as cerebral tumors and other diseases of intra-cerebral origin, but these do not fall within my category. Strictly speaking neuralgia is a painful affection of the nerve itself affecting either its origin, its course or its peripheral termination. It is essential to distinguish it from neuritis from which it differs in many important respects. What is spoken of in popular language as "sciatica," may be a neuralgia, but in the great majority of cases is produced by inflammation of the nerve fibers, and is a true neuritis. The pains of locomotor ataxy which so commonly affect the legs and are of the "lightning" variety, should not be described as neuralgia, although they may be "neuralgic" in type and character; they are the direct expression of the sclerotic changes which are taking place in the posterior columns of the cord. The same is equally true of many pains which roughly are classified as rheumatism or neuralgia. These terms are employed vaguely, and in a very indefinite sense, but the clinical

observer is more careful in his nomenclature.

With regard to symptoms, the pain is deep-seated, and corresponds to the position of a nerve-trunk, spreading along its course, or radiating with its branches. It is often one-sided, but it may be bilateral and symmetrical. It is shooting, stabbing, boring, burning, gnawing or throbbing; in its duration it varies considerably; it may last only a short time; for minutes or hours, and then subside entirely to return after an interval of weeks or months, or it may be continuous with exacerbations. After it has continued in one of these forms for some time, tender points may be recognized; spots on the surface of the skin, which are tender to firm pressure. They lie in the course of the affected nerve or its branches, and correspond to the point of exit of the nerve from a bone, where it perforates the fascia, where it passes over a hard surface, or where the nerve divides into branches, or where nerves anastomose. Another tender spot is frequently found, the point of Trousseau over the vertebral spine corresponding to the nerve affected with neuralgia.

There is marked tenderness of the skin over the painful part which may last after the subsidence of the pain. Occasionally muscular spasm takes place as a reflex effect in the region of the nerve affected, and vasomotor disturbances may be present, such as pallor, followed by flushing, sweating, lachrymation (in trifacial neuralgia), and edema. The hair may change color, or fall off, or it may grow in excess.

The evidence of diseases competent to produce pain in the region of the nerve affected should be sought for. The lesions likely to produce this effect vary in different parts of the body. Carious teeth may cause toothache, or without local pain may cause neuralgia in every division of the fifth nerve, or in the occipital region. Diseases of the bones and deep-seated tumors may involve the main branches of nerves. The cervical and brachial nerves are involved in caries of the spine. The brachial nerves are often the seat of neuritis. Intercostal pains may be due to disease of the ribs, caries or cancer of the vertebræ or spinal meningitis, tumors or aneurysm. Disease of the lumbar vertebræ, renal colic, and renal disease are responsible for pains in the area of the lumbar plexus, and sciatic pains are produced by disease of the sacro-iliac and hip joints, psoas abscess, pelvic tumors and tumors of the femur. Locomotor ataxy produces its shooting and stabbing neuralgic pains which are generally bilateral, and accompanied by other indications of the disease.

The pathology of neuralgia is obscure, but there is much in favor of the view that it is a disturbance of the nerve cells connected with the central end of the nerve trunk.

Neuralgia has been defined as the cry of the nerve for food, and undoubtedly in young people it is often due to anemia. The subjects are not infrequently young women who, as a result of defective social or hygienic conditions, suffer from amenorrhea, and whose erythrocytes, instead of numbering from four to five millions per cmm., are reduced to two million five hundred thousand, or even less, with a corresponding fall in hemoglobin value. Only too commonly they are the victims of chronic constipation and atony of the lower bowel. These cases, once recognized, are easy of treatment, and are amongst the most satisfactory which fall to the care of the physician. The first point is to regulate and improve the general conditions of the sufferer's mode of life. More exercise, fewer hours in bed, less stimulants, a regulation of the dietary and some serious course of work and intellectual employment are the key-notes to the situation. After that the bowels should be regulated and a copious evacuation should be ensured every morning, what particular agent should be employed for the purpose is a matter of little moment as long as it is effective; the homely domestic Epsom salts, the waters of the most frequently and largely advertised German Spa, or the synthetical products of the laboratory may be employed according to the idiosyncrasy of the physician or the length of pocket of the patient. The agent matters little, but the result must be attained freely and copiously. This paves the way for the administration of iron. For anemia of this type iron is the one and only remedy; arsenic and manganese and their various

combinations being of little or no avail. The form in which iron is administered is a matter of comparatively little importance, but personally I have a profound contempt for the scale perparations which, in my hands, have proved lamentably inefficacious. Whether an organic or an inorganic salt of iron be administered does not matter much, but the ferric and more astringent salts undoubtedly prove most efficacious. I do not wish to advocate any particular formula, but the following will, I think, be found useful:

℞ Tinct. Ferri Perchlor.....2 drachms.
Spts. Chloroformi .....1½ drachms.
Glycerini.....2 drachms.
Aquam.....ad.....8 ounces.
M. ft. mist. One ounce three times daily.

This should be taken three times a day, immediately after meals. Some people say that it should be sucked through a straw to prevent blacking of the teeth, but surely this is quite unnecessary. Then, again, some prescribers add to it sulphate of magnesium to obviate the possibility of constipation, but as a matter of practice it were better that the purgative should be given apart and distinct from the iron tonic. I am quite willing to admit that the addition of a few drops of tincture of belladonna or of tincture of nux vomica may be useful in stimulating the peristaltic action of the intestine, and possibly by increasing mucous secretion. A milder and less astringent preparation of iron is that known as Basham's Mixture. The formula I give is a modification of, and I think, an improvement on the original:

℞ Tinct. Ferri Perchlor.....2 drachms.
Liq. Ammon. Acet.....1½ ounces.
Sp. Chloroformi .....1½ drachms.
Syrup Limonis ..... ½ ounce.
Aquam.....ad.....8 ounces.
M. Sig.: Two tablespoonfuls three times a day after meals.

Here the iron is no longer in the form of the perchloride, but is converted into the acetate, which is very easily absorbed and assimilated. It is a powerful hematinic, and sends up the blood count, and the hemoglobin percentage by leaps and bounds. In cases of neuralgia dependent on anemia, it is a powerful therapeutic agent, and even when there is no obvious anemia it will often act as a stimulant to the functionally deranged nerves, restoring their power and alleviating the attacks of pain. In every case of neuralgia the possibility of a blood deterioration should be borne in mind, and even when a blood count is not resorted to the pallid condition of the mucous membranes of the lips and of the conjunctiva may afford a useful clue to treatment. It is useless to resort to what are called "specific" remedies unless the underlying constitutional condition is first taken into consideration. The physician who prescribes remedies for the names of diseases is but little likely to meet with success, and it is only by a broad grasp of the subject that curative measures can be adopted to individual requirements.

The site of the neuralgia, that is to say the nerve, or the branches of the nerve affected is often a guide to treatment. It is a matter of experience that supra-orbital neuralgia is very readily controlled by quinine. I do not think that it is important in what form it is administered, whether in a mixture or in a pill, or dissolved in sherry. The following is a familiar formula:

℞ Quininæ Sulph.....25 grains.
Acid Sulph. Dil.....25 minims.
Sp. Chloroformi ..... 2 drachms.
Aq. Cinnamomi..... 4 ounces.
Aquam.....ad..... 8 ounces.
M. Sig.: This should be given in two table spoonful doses three times a day, or every four hours if necessary.

When the branches of the fifth are involved Butyl-chloral-hydrate or tincture of gelsemium is indicated.

Another good remedy is chloride of ammonium, which should be given in forty-grain doses every four hours. It has a somewhat nauseous and bitter taste, which can, however, be more or less successfully disguised by the plentiful addition to the mixture of liquid extract of liquorice. I know of no particular guide or indication for the administration of this drug, but I do know that when it fails to effect a cure in forty-eight hours it is useless to continue it. In some cases it answers admirably, whilst in others it signally fails.

The internal administration of aconitine in the treatment of trigeminal neuralgia has been highly praised by Gübler and many other French authors, but its administration requires considerable care, and it must never be forgotten that while it is a very active alkaloid, it varies much in strength, this variation depending

partly on its source and partly on its mode of extraction. Speaking broadly, it may be said that the English aconitine is much more powerful than the French, and that the American crystalline form is infinitely more powerful than either. The following formula was introduced many years ago by Dr. E. C. Seguin:

Duquesnel's aconitine, from a twelfth to an eighth of a grain, alcohol and glycerin, of each a drachm, peppermint water to two ounces.

This forms a mixture of which a drachm should be given three times a day, cautiously increasing the frequency of administration until there is a commencing feeling of numbness, especially over the face. Directly this is experienced the administration of the drug should be suspended.

Phosphorus and arsenic I regard less as specific remedies for neuralgia than as agents which improve the general condition of the health and impart tone to the nervous system. There are many forms in which they can be conveniently given, but it is useless to expect a very rapid improvement, and their administration will probably have to be continued over a long period, possibly even for weeks or months.

There are many local applications which prove efficacious, and personally, I have a great regard for this liniment:

℞ Aconitine.....1 grain.
Essential Oil of Mustard.....1 drachm.
Glycerine.....1 ounce.
Rectified Spirit to.....6 ounces.
M. Sig.: Poison.

It must be applied sparingly and with caution, for aconitine is a very active poison; a fact, however, which should not preclude its use in skilled hands. The physician should always make the application himself, and never entrust the bottle to the keeping of the patient.

The unguentum aconitine of the British Pharmacopeia is another useful preparation for the relief of pain, and was introduced originally by Sir Benjamin Brodie. It, too, must be employed with caution, and only a very small piece should be smeared along the course of the painful nerve twice a day.

There are certain combinations of menthol which, painted on the affected part, speedily give relief, especially in facial neuralgia. I often use in this way menthol, thymol, chloral and camphor rubbed up together to form a syrupy fluid. Liniments composed of tincture of aconite, tincture of belladonna, tincture of capsicum and liniment of chloroform answer well, but if the belladonna is in excess it is apt to dilate the pupils and put the patient to temporary discomfort.

The custom has sprung up of late of using a one per cent solution of osmic acid, hypodermically, in the treatment of some forms of neuralgia, those especially affecting the branches of the fifth nerve. I have used it in a number of cases, and I can not speak of it enthusiastically. It must be used with caution, especially in the case of mixed nerves like the sciatic.

Change of air is undoubtedly beneficial in chronic neuralgia and neuritis, but much care has to be taken in the choice of a residence. Plenty of sun is the great desideratum. High altitudes, bracing air and the seaside usually increase the pain. I send most of my patients to Spa in Belgium. It is only a few hours' journey from London, Paris and Brussels. It is a bright, cheery little place, surrounded by pine forests, and the hotels are as good as any in Europe. Moreover there are the iron springs, the waters of which exert a beneficial effect in anemia.

Baths are useful in all neuralgias except those of the face. The bath must be hot and prolonged. The Balneum Alkalinum of the Guy's Hospital Pharmacopeia, containing four ounces of sodium carbonate in thirty gallons of water, may be used as a basis, but I usually add a suitable quantity of pure terebene, or some similar aromatic, or pine preparation. The effervescing carbonic acid baths of Spa are excellent, but they must be taken on the spot, for it is natural, and not artificial gas.

Operations, such as excision of a portion of the nerve, stretching or harrowing the nerve, or the removal of the nearest ganglion, may effect a permanent cure, as I have often seen, but these modes of treatment should not be resorted to until all other measures have been exhausted.

Can't get along without The Medical Brief.—J. A. Smith, M. D., Norway, Ia.

Report of a Surgical Clinic.

BY A. SHIMONEK, M. D.,

Clinical Professor of Surgery in the Medical Department of Hamline University. St. Paul, Minn.

Case 1.—This patient, a lady of forty-six, sustained an injury to the left shoulder by being thrown out of her carriage. Examination by a physician, at the time, was negative. She was able to carry the joint through all its motions without much pain. In the course of a week or so the shoulder would ache on motion, and its range of mobility was interfered with. This condition of affairs continued to increase; the movements of the joint became more and more limited, pain developed even when the shoulder was at rest, until now, three months after the injury, she presents herself to us for aid.

The treatment at home was that of rest and counter-irritation. I have examined her on two occasions, and find that the joint can not be moved much, if any. The motion she shows is due, largely, to the mobility of the scapula. The musculature around the joint is sore and tender, but there is spastic contraction of the muscles. Pain is an important feature, radiating into the forearm and fingers. This prevents her from using the arm during the day, and from sleeping at night. Examination of the joint, together with fluoroscopic picture, excludes dislocation, fracture, and disease of the bone. Besides a little atrophy of the joint, nothing abnormal is to be found. Now, what is the condition of affairs, and what shall we do for the patient?

In the absence of any positive lesion, and the exclusion of rheumatism, a condition like this not infrequently follows slight injury, in which a slow form of inflammation develops and cripples some of the structures of the joint proper. In all probability we have a periarthritis. An affection, firstly, of the subacromial burse, with thickening of its sac walls and adhesions, preventing the superior part of the head of the humerus from rolling out over the tip of the acromion process of the scapula. This interferes with the upward motion of the shoulder joint. In all probability there is inflammation of the areolar tissue under the deltoid muscle, and, probably, an inflammatory condition of the musculature of the joint or myocytis, evidenced by the soreness and tenderness of the outside of the joint. These pathological lesions are responsible, to a great extent, for the immobility of the joint. The exudate and adhesions produce pressure and, probably, neuritis of the joint, which accounts for the pain, and the uselessness of the arm.

The treatment of a case like this is not rest, at any rate not a prolonged rest, for this favors anchylosis of the joint. It is action that is needed, and while the case has gone on this long, adhesions must be broken up under anesthesia, which we will do. Under anesthesia there is "snapping" under forcible motion, as the fibrous adhesions give way. This is followed by quite good rotation, giving the elevated and forward and backward motion. The after treatment is all important. For twenty-four or forty-eight hours we will allow the joint to rest after breaking up the adhesions, and then use intelligent massage and passive motion daily. In time the joint will be considerably improved, if not completely, though we must not promise the patient too much, for there are disappointments sometimes in such cases. If the joint stiffens up very much it may be necessary to loosen it again under anesthesia, and, probably, a third time. In these cases, if the patient does not grow discouraged and the physician treats them intelligently, a useful joint will result.

Case 2.—A lady, fifty-three years of age, gives a history of stomach trouble, extending over a period of twenty-five years. Her suffering has not been constant. She would have periods of what she called absolute health, for weeks and months at a time. Her family history is good, except for one relative who succumbed to gall-stone disease. She describes her periodical trouble as one of indigestion, followed by pain, nausea, and sometimes vomiting. She thinks she has had colicky pains once or twice, but never any pronounced colic. She has never been incapacitated for work, but had always to be careful about her diet. Any food not agreeing with her seemed to remain a

long time in the stomach, and cause eructations of gas for hours. Her present trouble commenced six weeks ago, with symptoms like her previous ones, followed by chills, fever and jaundice—prominent features in all her attacks.

I have examined her a number of times during the past week and find a poorly-nourished, emaciated, jaundiced woman; tongue coated, temperature runs from normal to 100° F.; pulse, rather rapid. Otherwise nothing unusual can be elicited. Over the gall-bladder area there is a tender region, and when the fingers are pressed in during inspiration and held there until she is asked to fill her lungs, she suddenly stops breathing, or rather the respiration suddenly comes to a halt on account of the severe pain. This is, in all probability, due to an inflamed gall-bladder, which comes in contact with the tips of the fingers. There is a sensitive spot directly back of the liver, a prominent feature in a great many cases of gall-stones. From this history and the symptoms, I believe we can reasonably make a diagnosis of cholelithiasis, cholecystitis, and an obstruction of the common duct by the stone. A straight incision was made in the right rectus muscle through the peritoneum. The examining fingers came directly in contact with a small, thickened, contracted gall-bladder containing stones. In the common duct above the duodenum is a good-sized stone, easily palpated. On account of the crippled condition of the gall bladder, I proceed to remove it. In order to have room for manipulation, the incision was enlarged by carrying it upwards and inward along the costal arch, making the incision known as the Mayo-Robson incision for gall-stones. Sometimes, if we are unable to elevate the duct sufficiently to reach the stone, it may become necessary to reach the liver by bringing it down below the ribs as far as possible, and then turning it upward, which, in some instances, will bring the ducts in a straight line, and almost on a level with the skin incision. Before making the incision into the common duct it becomes indispensable to pack away the peritoneal cavity. The next step is to pass the fingers into the foramen of Winslow, lift the duct, make an incision into it directly over the stone, when we now extract a large dark-green stone, with a number of prolongations. Then we make a thorough search, first, with the sound passing upwards toward the hepatic duct, and again downwards, back of the duodenum, for the purpose of discovering other stones. The sound is not always the surest means for this purpose. If the duct is sufficiently dilated, it may be necessary to introduce a finger upwards and downwards in order to locate stones higher or lower in the duct. However, the ordinary means of palpating the ducts outside is, in the majority of cases, sufficient to determine the presence or absence of stones. The recognized treatment of all of the best surgeons is that of drainage, which we will utilize in this case. Drainage is indispensable when the gall-bladder has been removed and duct opened. A tube the size of a small pencil is introduced upwards towards the hepatic duct, a cat-gut suture is passed into the incision below and above, and one through the tube and the duct to hold it in place. The pack walling, off the peritoneal cavity is next removed and a number of cigarette drains introduced, inwardly, outwardly, below and above the drainage tube, and we proceed to close up the peritoneal cavity. The drainage tube will be conveyed into a sterilized bottle (six-ounce size), which is incorporated into the outside bandage, and held there by adhesive strips. This drainage tube will remain in the duct until such time as the catgut suture which holds it in place is absorbed, which is from five to ten days. By that time the peritoneal cavity will have been sufficiently walled off to prevent the leakage of bile into it. Gauze packing, loosely applied, will be passed into this opening until granulation is complete.

Case 3.—Seven weeks ago this young man sustained an injury by forcibly falling on his right knee. Examination, a few hours after injury, showed a fracture of the patella. A fracture like this one can be produced by direct violence, or can occur simply by muscular action. The line of break may be transverse, oblique, vertical or stellate. This particular one is transverse. More or less hemorrhage takes place into the joint, following injury, and as a result of the formation of

blood clot, the synovial secretion is increased, so that we, ordinarily, have considerable effusion into the knee joint, resulting in a swollen and painful knee. We must not lose sight of the fact that in an old patient, with low vitality, generally this clot sometimes becomes infected, either from without, or through the blood within, and results in serious consequences. Fortunately, this is rare and occurs mostly in open fractures.

A thorough understanding of the method of treatment, be it conservative or operative, is indispensable to good results. In considering the operative treatment, or that of opening the knee and suturing the fragments together, we must not forget the possibilities of infection, with such serious consequences as complete anchylosis, amputation, and even death. If the synovial tissue in the knee joint were as invulnerable as, for instance, the peritoneum, which can take care of a goodly amount of sepsis, and we are sure of our asepsis, then the matter of treatment could be settled in favor of suturing in every instance. Before undertaking the operative treatment, this must always be laid before the patient. There is no doubt that the operative method is far superior to the nonoperative, and lays up the patient for a much shorter period of time, an important factor to a laboring man. Let no man make light of opening the knee joint, and let him only who is master of aseptic surgery undertake the operative treatment of fracture of the patella. This patient preferred and accepted the non-operative treatment. Elevation of the leg in a splint, ice packs, with moderate compression to favor absorption of the effusion. After six days, when this was accomplished, a long posterior plaster of paris splint was made, reaching from the upper third of the thigh to below the patella. The lower fragment of the fracture was raised as high as possible with a strip of adhesive plaster pulling upward; then the upper fragment was pulled down and coapted to its fellow, as well as possible. A long strip of adhesive plaster, pulling downward, was applied. A well-folded compress was placed over the site of the fracture, from which another band of adhesive plaster was applied, the direction of pulling being directly upwards, for the purpose of preventing the tilting of the fragments upwards. To keep the quadriceps extensor muscles at rest and relaxed, a curved splint, well padded, was applied over it, and held in place by adhesive plaster strips. This apparatus was inspected daily, being kept constantly in an elevated position. After the second week daily massage was employed to prevent atrophy. At the end of four and a half weeks this apparatus was substituted by a plaster of paris bandage enveloping the whole limb, and extending as high as the groin. At the end of three weeks it was split anteriorly, and passive motion and massage was used and is still being used. The fragments are now in pretty good apposition, and we have already a good range of motion. At the end of three months all apparatus will be removed, and only a firm cotton, or better, an elastic webbing bandage will be applied, and he will be allowed to walk with the aid of a cane, holding the limb in an extended position. The union, after such treatment, is mostly fibrous, due, probably, to the intravention of the anterior part of the capsule between the fragments. The union after good suturing is often bony and, therefore, superior to the non-operative treatment.

These patients must be told to be extremely careful in walking, for the knee remains weak for a long time, probably nine months or a year, or more. Should the fragments, under this treatment, become gradually separated or non-union take place, a resort to operative treatment is necessary.

Case 4.—The history of this little girl, ten years old, is rather indefinite. Her father states that fifteen months ago she became sick, with pains in the abdomen, fever, lack of appetite, emaciation, and, sooner or later, effusion into the peritoneal cavity. This condition of affairs persisted for a long time, and she was under the care of physicians who pronounced the case, in all probability, tuberculosis. She lingered for months and, eventually, made a fair recovery. She was sent to a child's asylum and, sometime after, had an attack of very severe colic.

She was seen by a physician, whose diagnosis we do not know. She continued

to have pain in the abdomen, fever and chills until a swelling occurred in the median line, midway between the symphysis pubis and the umbilicus, which raised to the size of a hen's egg. This was opened and discharged a large quantity of foul-smelling pus. This opening has remained up to the present time. Some months ago she was treated for this sinus by dilating it, washing, etc., and it was found that the fluid passed into the rectum. The father states that one of her physicians was able to pass a strip of gauze through the opening and out through the rectum.

On examination, the sinus is that of a small opening in the median line, admitting a probe, which can be passed down for a length of five inches.

The only possible hope of a complete cure in a sinus of this character, is the opening of the abdominal cavity and following the tract to its bottom, excising it. This may be a formidable task, inasmuch as the inflammatory process which led to the formation of the opening, has, in all probability, created extensive adhesions betwen the bowels and the sinus. We will begin this proceeding by first passing a probe as far as it will go, packing absorbent cotton around it, and applying a coat of collodion, which will prevent any of the septic material from entering the peritoneal cavity during the attempt at removal. The sound in the sinus is an important thing, inasmuch as it will act as a guide to the operative procedure. I now make a median incision above the sinus, carrying it around the fistula on both sides, and down the median line below the sinus. We must be extremely careful in separating the fistulous tract, because of the probable adhesions of the intestines to the walls of the fistula throughout its whole length. After having entered the abdominal cavity on all sides, keeping the fistulous tract, with its guide well elevated, I find that we have cut through a loop of intestine, and will proceed at once to close it up with a Lembert suture. The intestine was so intimately adherent to the sides that it was almost impossible to make a separation without wounding it. Below the fistulous tract I found a large, flat and flabby mass, adherent for several inches to the tract, and as the mass seems to lead back of the symphysis pubis, I am suspicious that it is the bladder. To remove all doubt I have one of the assistants pass a long probe into the bladder through the urethra, and find at once that it has passed into the mass, corroborating my suspicion. My next step is to separate it from the fistulous tract. On account of its intimate adherence I have already cut through the bladder for a distance of one inch, which I will immediately close by a double row of sutures, and then proceed with the separation. I am now able to pass the fingers below the attachment of the bladder, bringing them up and elevating the bladder, so that I can make a separation without any further injury. I find that the bladder is free from the lower part of the fistulous tract, and we will allow it to drop into its place in the pelvis. I have raised the fistulous tract, with its adhesions, almost out of the abdominal cavity, and in doing so I find that I have torn, probably, the ascending colon, which will be stitched immediately by continuous Lembert suture. I find that in making the separation I am breaking into the fistulous tract constantly. However, it has been sufficiently sterilized with pure carbolic acid so that we may not expect very much infection from it into the general peritoneal cavity. After dissecting out the tract to the extent of three or four inches, I suspect that it leads into the sigmoid flexure or the rectum which suspicion was verified by an assistant passing a long, straight sound into the rectum, showing a discharge of blood from the rectum, signifying that the sinus is in direct communication with that portion of the bowel. This simplifies matters, in that I am down to the opening in the large bowel on the left side, and will now remove the guide and proceed to close up the opening in the bowel. I find there is considerable exudate around this opening, and the stitches do not hold, so they will be passed quite a distance from the opening, and the perforation turned in, and over it, we will sew the sutured pieces of omentum in order to strengthen the perforation. The fistulous tract is now practically removed, and the opening in

the rectum closed, drainage is secured through two good-sized cigarette drains, and the abdominal cavity is closed. If this patient does not become infected by the injury done to the intestine, and she recovers from the immediate effects of the operation, I believe that she will be permanently cured.

Case 5.—An acute case of appendicitis. The first attack commencing last Sunday night, characterized by sudden and severe pain in the epigastric region, after some hours radiating down towards the ileocecal region, accompanied by vomiting, and followed by a rise of temperature. He was seen on Monday morning and a hypodermic injection of morphine given for pain, and for some reason the operation was delayed until now. He has a temperature of 101° F., with a pulse of one hundred and twenty; he is slightly jaundiced, and has moderate commencing distention of the abdomen.

In considering the subject of operative procedure in acute infections of the appendix, the sooner it is done the better. Say, within a few hours after the attack, or up to forty-eight hours, being, probably, the best time to operate.. If the patient, after the third day, is suffering seriously from an infection outside of the appendix, it is probably the better plan to carry out the conservative treatment of no feeding, ice packs and a little opium to relieve the pain, until such time as the disease becomes localized by nature. This may be after six or seven days. In this particular case we are operating sixty hours after the attack, and it is probably well that we have, for we find a gangrenous appendix, with pus in the peritoneal cavity. This patient is slightly jaundiced, and his expression is that of one who is considerably infected. I do not think the waiting plan, in this case, would be of any especial benefit, as the appendix is gangrenous. No elaborate amount of work is necessary in the matter of inverting the appendix into the cecum here, on account of the exudate, and the softened condition of the parts. Drainage is an indispensable feature in a case of this kind, and I will pass three cigarette drains, consisting simply of a rolled piece of gauze, with a rubber tissue around them down back of the cecum, and put in a few stitches into the abdominal walls. We have such free drainage here that I am hopeful that a general septic peritonitis may be avoided.

Defiel Building.

[Written for the MEDICAL BRIEF.]

Differentiation of Variola Simplex From Varicella.

BY N. C. SCHILTZ, M. D.,

Professor of Internal Medicine and Physical Diagnosis in Drake University College of Medicine. Des Moines, Iowa.

The following differentiation is made from the appearance of the eruption, excluding all constitutional symptoms and history of the case.

In small-pox the eruption usually makes its appearance on the fourth day of the disease, is papular in character, with a shot-like hardness, occurring first, usually, on the face and wrists, then extending rapidly over the general surface and the extremities, including the palms of the hands and soles of the feet. Within the next day or two the papules change to vesicles, with turbid fluid contents, and continue to increase in size. The next two or three days a pustule is formed. The vesicle gradually increases in size to that of a split pea or larger, and their uniformity of size is quite characteristic. Many vesicles are slightly umbilicated in the center. This umbilication is very characteristic. The wall of the vesicle appears thick and leatherlike. The tension within is great, therefore the vesicle is hard, resisting and painful. Puncture of the vesicle with a needle does not cause its collapse, nor does the fluid all escape. This is partly due to the peculiar structure of the vesicle and the thickness of its walls. The base of the vesicles is perfectly round, with a dull red areola about them, and soon become grayish-yellow in appearance, losing their umbilication, and change to pustules. After the second or third day the pustule desiccates, causing the secondary umbilication, and in a few days a crust has formed which, later, drops off and leaves an ulcer, varying in depth according to the severity of the disease and the amount of irritation to which the lesion has been subjected. The prominence of the scar depends upon the depth of the destruction of tissue by ulceration—some-

times leaving little or no scar, and in other cases very marked pitting.

In varicella the eruption appears within the first twenty-four hours after the first symptom of the disease, and not infrequently no symptom has been noticed until the eruption appears. The eruption appears as pimples, and in a few hours the vesicles are formed, with or without a bright-red areola. The vesicles continue to appear in successive groups for several days, and when the last appears the first lesion may desiccate. These vesicles are brilliant in appearance. They vary in size in the individual affected, some as small as a pin's head, while others may be as large as a ten-cent piece, and are for the most part angular, instead of round, as in discrete small-pox. The vessel wall is very thin, and collapsible and wrinkles when the contents are let out. One puncture drains the whole vesicle. At the end of the second or third day some of the lesions begin to desiccate, while others are just beginning to form vesicles. These groups of vesicles may continue for several days, or a week. There is no primary umbilication, but occasionally an umbilication, due to the desiccation in the center of the vesicle, occurs. This in small-pox is called the secondary umbilication. Rarely, if ever, does this eruption appear on the soles of the feet or palms of the hands. It is, moreover, a disease of childhood and very rarely occurs in adults.

Infant's Cry in Utero—Can It Be Heard?

BY B. P. WATTS, M. D.,
East Galesburg, Ill.

I have frequently heard persons say (one an old medical man) that they had heard the infant distinctly cry in utero many days before the termination of gestation. I have been in active practice of medicine, and have had abundant experience in obstetrics ever since I was eighteen years old, and am now fifty-seven, and I have failed to meet with such an experience, and can not believe it was the infant they heard. Is it possible? Will the editor or some of the many BRIEF readers inform me.

[Written for the MEDICAL BRIEF.]

Observations Upon the Course and Treatment of Three Cases of Epidemic Cerebro-Spinal Meningitis, Spotted Fever.

BY J. B. KINLEY, B. SC., M. D.,
Dean Denver Homeopathic College and Professor Theory and Practice in Same.
Denver, Colo.

The purpose of this article is to show the course and treatment of three typical cases of cerebro-spinal meningitis. The first case was that of R. P., aged ten years, a boy of unusually good constitution, good habits and appetite, never had been ill but once in his life, that was a slight attack of pneumonia about two years ago. The family history is particularly good. He was taken ill about midnight of March 29. He went to bed the night before in comparatively good health, waking his parents about midnight because of a violent headache; this increased rapidly until he was partly unconscious. I was called about 3:30 o'clock that morning. I found him suffering with extreme prostration, projectile vomiting, wild and violent delirium, screaming at short intervals so violently that I heard him two blocks away. On examination I found his skin hot, semi-conscious, constantly moaning; pulse, one hundred and twenty; temperature, 101° F. Opisthotonus of the most extreme form that I had ever seen. He was drawn back, forming a half circle. I prescribed stramonium, 3x; I called again about nine A. M. that morning and found the entire body covered with a petechial eruption; color, purplish or bluish, two spots appearing like a ecchymosis, two inches in diameter. Severe myalgic pains, hyperesthesia general. At this time I sought Kernig's signs and Babinski's reflex, and found both very prominent. All symptoms had increased, except the opisthotonus, which was now slightly relaxed. I continued the same treatment, but used, in addition, an ice cap. On March 30, no improvement, except a little more relaxation of the opisthotonus. On the following morning I found the facial muscles in extreme rigor. There was an appearance on his face, as of great fear,

mingled with pain, but no consciousness. The appearance of this boy was one that I shall never forget. It is said that Dore, in making the illustrations for Dante's Inferno, took for his subjects patients which he had seen suffering with the plague. I think he could not have seen spotted fever, the expression was so much more terrible. At this time the opisthotonus had partly relaxed. There had been no movement of the bowels. A high enema succeeded only in bringing a few very hard, black lumps of fecal matter, about the size of a hazelnut, appearing as if they had been burned or baked. I discontinued the stramonium and prescribed instead, opium, 30x. Temperature had now fallen to 99° F., the eruption was fading, there was stertorous breathing, very much resembling the Cheyne-Stokes breathing; the pupils were contracted, there was diplophobia, with ptosis.

On April 3, temperature was 100° F., the pulse weak, one hundred and thirty; prostration increased, the patient was extremely restless; he was now partly conscious and continuously crying out. I prescribed arsenic third. Two days afterward the prostration was lessened. The joints were exceedingly painful and swollen, having the appearance of acute arthritis. I prescribed cimicifuga. His symptoms improved, but the restlessness increased; cerebration slow; emaciation increased. He became very thin and weak. Bed sores, with a purple base, and sloughing appeared on his hips and back. His appetite was good, but there was practically no taste; castor oil or beef tea tasted the same to him. He had no knowledge of what he ate, and was constantly hungry, yet his emaciation continued, and evacuation of the bowels could only be had by giving a laxative or enema. From this time on his treatment consisted of cicuta vir.

This boy's condition, physically as well as mentally, remained practically the same for four weeks, at the end of that time, and at the present time, his mental condition is very slightly improving. Physically, he is gaining a little in flesh, his bed sores are healing, but his knees are bent, causing him great pain when his mother attempts to straighten them. At this time it is very uncertain as to whether he will or will not recover. In the last two weeks I have prescribed for him iodide of arsenic, 3x, with apparently fair results.

Case 2.—C. L., a boy, aged eleven; very bright mentally, but not particularly strong physically. He has never had a severe illness. His father came to Colorado because of asthma, with a tubercular tendency. His mother is healthy. On April 24, I was called at four o'clock in the morning and found the boy unconscious, screaming with what seemed to be pain in the head. His screaming very much resembled the hydrocephalic cry. He had vomited severely; opisthotonus was present, although not as severe as in the former case. Pulse, one hundred and thirty; temperature, 102° F. I prescribed stramonium, as in the former case. On the evening of the same day I found the opisthotonus somewhat relieved, consciousness had partly returned. He complained of extreme headache and backache, which he afterward explained was in the spine. There were the typical eruptions, but few in number, probably not more than twenty petechial spots. I discontinued the stramonium and prescribed cicuta, instead. The next day I found him practically the same, with diplophobia present. Hyperesthesia very great. Cheyne-Stokes' breathing very marked and threatening to stop breathing altogether. At times he would stop breathing entirely, and his mother would revive him by shaking him or slapping his face with a wet towel. Constipation, as in the former case, was extreme. The same burned-appearing stools, resulting only from enema; the pupils were contracted. Kernig's sign and Babinski's reflex present, but not as pronounced as in the former case.

I prescribed opium, 30th, in alternation with cicuta. The following day he had a full stool; opisthotonus had disappeared. His temperature was 100° F., pulse still one hundred and thirty; great restlessness and prostration now appeared. Emaciation began, vomiting had ceased, screaming but seldom, pain in the head and neck not as severe as before.

On May 1 he had decidedly improved, but more restlessness, more emaciation, no appetite, hypersensitive, pains in the joints of an arthritic nature. I again pre-

scribed cimicifuga, which in two days relieved the arthritic pain, but did not improve the general condition. I again resorted to cicuta, which, after one week, seemed to be of considerable value to him until about the middle of May, at that time I changed to iodide of arsenic, which, after one week, seemed to restore him to almost normal condition. I discharged him, cured, on May 26. Since that time I have seen him repeatedly, but have found no necessity for further treatment.

Case 3.—P. S., aged sixteen years; a very ardent student, carrying two grades in his school at one time. His teacher considered him one of the brightest students in her school; no ailment for several years, but at the age of three had had a severe attack of scarlet fever, from which he recovered nicely, except an impediment in his speech. He was rather large for his age, of athletic build. This boy was physically and mentally in excellent condition.

On May 26th, he was taken ill with spotted fever, with two others of his school. One of his schoolmates died within forty-eight hours. I was called at noon of the day he was taken ill, but, not thinking that the boy was severely sick, I did not see him until six o'clock. I found him delirious, talking continuously of his studies and sports, and complaining very severely of pain in the index finger of his right hand, which he had bruised the day before, but upon which there was practically no abrasion. Vomiting was severe, pulse one hundred and twenty-four; temperature, 101.2° F.; opisthotonus quite severe. I again prescribed stramonium, with marked benefit. On the following day he had extremely severe pain in the head and neck; delirium. His father and older brother being compelled to hold him in bed all night, owing to his constant desire to leap from the window. His attention seemed to be directed to one window, but his attendants succeeded in getting him back to bed.

I prescribed sodium bromide in five-grain doses every hour until three doses were taken. He became somewhat calm, but his mind was very much affected. His delirium would recur at short intervals, and his opisthotonus was now very much relieved, yet a little bending of the neck remained for at least ten days.

On the third day I put him on cicuta, as in the former cases. His delirium gradually calmed, but the pain in the head and neck seemed to increase, so that he would scream wildly, even more so than the two previous cases. The petechial eruption, in this case, was less than in the others. We found only twelve spots and none of these very large. After the fourth day they gradually disappeared, and his symptoms also diminished. He improved very nicely until the end of ten days, when a second fever appeared; temperature, 104° F.; pulse, one hundred and forty. He again became delirous, but no opisthotonus. The Cheyne-Stokes' breathing appeared, but mildly. The symptoms readily yielded to cicuta. Immediately after this the arthritic pains appeared in him, as in former cases, but soon yielded to cimicifuga. From this time on his recovery was good. He did not become as much emaciated as either of the other cases. His mind cleared up rapidly, and his physical strength increased so that at the end of one month, he was well.

Observations.—I wish to call particular attention to the fact that in each of these cases the hygienic conditions were somewhat similar. Two of them living in frame houses, standing very near the ground. Sanitation not modern, although not poor in either case. In the home of Case No. 2 the sanitary conditions were fair, but their flat was in a basement. In each of the three cases modern sanitation was absent.

Another feature that I wish to call attention to is, that in each of the three cases Kernig's sign and Babinski's reflex were present, and aided much in arriving at a diagnosis. In each case the petechial eruption was present, but in proportion to the severity of the cases. Babinski's reflex was also proportioned to the severity of the case in Case 1, which was by far the worse; even at this time the great toe of the right foot is almost constantly at right angles with the foot, although it relaxes at times.

Another feature, is the same form of constipation, and inability to get a movement, except by high enema or cathartics,

and the best result in each case was obtained by opium 30x, which produced in each case a satisfactory passage. The remedy, cicuta, was given in each case, and was very satisfactory. When the time came for completing absorption in the meninges of both the brain and spine it was necessary to change to the iodide of arsenic, and this last remedy did its work in each case satisfactorily, except the first, which even now bids fair to recover.

The diagnosis in case No. 1 was corroborated by Dr. W. H. Sharpley, Health Commissioner of Denver. Dr. J. W. Craig attended each of the three cases for me for four days during my absence. Dr. A. C. Stewart saw all of the cases with me, in consultation, when the matter of the probable loss of mentality became an alarming feature, but now it appears that while two of them have completely recovered, both mentally and physically, it is also probable that the third may recover.

[Written for the MEDICAL BRIEF.]

Blood Making.

BY J. M. KEYS, M. D.,

Formerly Dean of Lincoln Medical College of Cotner University and Professor of Practice of Medicine in same.
Omaha, Neb.

We hear much about good and bad blood, and blood-making among the laity, especially in the spring time, when they resort to all sorts of drugging in order to rectify some imaginary wrong of the blood. Just why they should require special treatment for the blood in the spring is not quite clear. Some insist that the blood is too thick; others say it is too thin, but all agree that blood medicine is necessary. This affords an opportunity for the druggist to show his interest in the welfare of the public by furnishing them with a full stock of blood medicines.

Judging from the usual prescriptions the majority of physicians have not improved much on the methods practiced by the laity and the druggist in regard to blood-making. If the modern doctor be consulted he will look wise, assume an air of profound mystery while he takes the family history, and then procure a few drops of blood for microscopic examination. This is followed by a very scientific report of the number of red and white corpuscles, and the usual prescription of some compound of iron. Of course, this scientific knowledge is valuable as well as impressive, and the patient readily pays the fee demanded.

It is surely time to be getting away from these relics of the past. The sooner the doctor realizes that iron and other drugs do not make blood, the better it will be for him and his patients. Then how shall we make blood? There is only one way, and that is the physiological one. There must be complete digestion and assimilation of food, and in addition to this the proper food. If this be true then the process of blood-making depends on any means that will promote digestion and assimilation, and not necessarily on medicine. Hygiene, massage and mental or suggestive therapeutics have a place here. Any departure from the natural or physiological standard of health must be noted, and the proper means used to correct it. There may be some wrong of innervation or circulation; some derangement of the glandular or lymphatic system; and often excessive acidity or alkalinity of the secretions of the blood itself. Besides this, retrograde metamorphosis may be slow from deficient cellular activity, leaving the system burdened with waste matter.

Now, in order to intelligently use remedies we must have some definite knowledge of pathological conditions, and not merely names of disease. The condition of the blood may be judged by an examination of the parts that are freely supplied with it, such as the mucous membrane and tongue, as well as the skin and its veins. It may be shown by weakness, pallor and lowered temperature, or a clear, waxy color of the skin, with a tinge of yellow or green, as in chlorosis. Another means of diagnosis is by the use of the microscope to determine the relative number of red and white corpuscles. But this usually results in the same old routine treatment of iron and tonics without regard to the cause. To the specific medicationist the relative number of red and

white corpuscles does not mean much, as it only shows the result of some derangement, while it gives but little, if any idea, of a remedy or the location of a lesion. All modern authorities agree that the blood should be slightly alkaline, and that the pabulum, when ready for absorption, must be the same in order to make good blood. If, at any time, the blood plasma becomes acid a retrograde change takes place in the body, and all the alkaline cell-salts are withdrawn from the tissues—a condition which takes place in all continued fevers to a greater or less extent. On the other hand, there must be an acid condition of the contents of the stomach to digest albumin and fibrin of meats and gluten and starch of cereals. If this become excessive digestion is impaired, both in the stomach and small intestines. The acid or alkaline condition may be known by the color of the mucous membrane of the mouth and tongue, or by the secretions, and indicate the remedy for each. The pallor of the mucous membrane with white coating of the tongue requires sodium potassium or magnesium salts, and occasionally the calcium salts, while the increased color demands the fruit or mineral acids, and sometimes iron and the special sedatives, in small doses. We would select them as specifically indicated. Phosphate of sodium 2x should be given when there is pale mucous membrane, acidity of the stomach and acid secretions. Magnesium phosphate 2x is the remedy for fermentation and pain in the stomach and small intestines, and for constipation. It also increases digestion and assimilation of food.

Calcium phosphate 3x is a valuable aid to tissue building and blood-making after exhaustive diseases or loss of blood, and as an aid to the digestion of fatty foods.

Postassium phosphate 3x increases innervation when there is great mental strain and insomnia, with muscular weakness. This remedy has no equal in these conditions. It has an affinity for the brain and nerve centers, and will restore and maintain normal activity.

Magnesium dioxide 1x is one of the late remedies not in general use. It increases oxidation and prevents fermentation and decomposition of food in the stomach and bowels, while it facilitates the elimination of waste products. This is one of our best blood-makers, and should be in general use.

For the opposite condition, showing increased color of mucous membrane and dark coating of the tongue, inclining to dryness, the acids are indicated. The fruit acids, or lactic acid, are indicated in all milder cases, while the dilute hydrochloric acid is preferable in chronic cases, showing dry, red tongue without coating, but in order to get best results it must be thoroughly diluted with water, one part to a thousand, assist digestion and assimilation of food, while any stronger preparation retards digestion. Baptisia is indicated in all cases showing a tendency to decomposition and the formation of ptomaines or toxins. Its action on the intestinal mucosa and glands renders it valuable in intestinal indigestion when indicated.

Among the prominent glandular remedies are the following: Phytolacca, rumex, iris, polymnia, ceonanthus, chionanthus, chelidonium and podophyllin, in small doses. These act on the liver, pancreas, spleen and other intestinal glands. It has been demonstrated by recent investigation that the action of these glands and lymphatic system destroys toxins in the blood, and completes the elaboration of food after it has reached the circulation. As the intestinal digestion is frequently defective, and must be supplemented by the glandular and lymphatic system, the action of these glands becomes very important in assimilation and blood-making.

The quality of the blood should not be judged by the relative number of red or white corpuscles, but by the quality of plasma. The blood plasma must furnish everything for the nutrition and repair of the body, and nothing can be carried to the tissues in any other way. While the red corpuscles only carry oxygen to the tissues, and in return receive carbon dioxide. They only carry what they get from the air, and the product of combustion and no nutriment for tissue building. The blood plasma is the most important factor in blood-making as well as tissue building. It carries both oxygen and nutrition to the cells by permeating the

inter-cellular spaces where neither the white nor the red corpuscles can pass.

Now if this be true then it is much more rational to direct our remedies to the correction of defects in plasma making, and leave the red and white corpuscles to take care of themselves, as the plasma must furnish the necessary material for the production of both.

Notes on the Pathology of Placenta Previa.

BY W. H. WENNING, A. M., M. D.,

Professor of Clinical Gynecology, Miami Medical College, Cincinnati; Professor of Gynecology, Cincinnati Polyclinic.
Cincinnati, Ohio.

The placenta may be said to be previa when it is inserted wholly or in part to that portion of the lower uterine segment which is subject to distention in pregnancy or labor.

In accordance with this definition the locality and amount of implantation will further determine the variety or form of placenta previa. The typical variety is that known as placenta previa centralis, in which placental tissue covers the os uteri over its whole periphery. A better term, therefore, is "placenta previa totalis," or complete placenta previa. By lateral or partial placenta previa is meant a condition in which placental tissue covers the os internum only in part; it is, therefore, an incomplete placenta previa. Marginal placenta previa is simply a low insertion of the placenta, but sufficiently high that its margin reaches to, but does not cover the os internum. While the onset of hemorrhage, the amount of blood lost, the time of its occurrence, are all of the utmost clinical importance, we can arrive at a true understanding of the facts only when we approach the subject from an anatomical standpoint. The normal development of the uterus in pregnancy, with its contents, the impregnated ovum, must first be thoroughly understood before we can fully appreciate any deviations from the normal.

The uterus of gestation is divisible into three parts, anatomically and physiologically distinct from each other when pregnancy nears its end. The body of the uterus is divided by the contraction ring into two parts, the cervix forming the third. The physiological function of the cervix proper becomes operative only during the progress of labor itself. It is well known that when the ovum enters the cavity of the uterus it is most apt to be caught in a fold of thickened decidua, near, but below the orifice of the uterine ends of the oviducts. We have, therefore, a cavity of considerable dimensions in the upper part of the womb. Normally the ovum is arrested at a spot not far below the entrance of the tubes. This is evident from the fact that in the great majority of instances the placenta has been found attached to the side of the uterus. If the ovum strikes the most dependent part we will have the lowest insertion of the placenta. If the ovum does not fall quite so low, but at a point near the border of that ring, which afterwards becomes the contraction ring, we have a lower implantation of the placenta. But in both instances we shall encounter a placenta previa, the situation of the ring of Bandl determining whether it shall be previa wholly or in part. If the placenta remain partly above and partly below this ring, we have a partial or incomplete placenta previa. If, however, the placental attachment be entirely below this ring, we shall have a total or complete placenta previa. In consequence of the distention of the lower segment in the last months of pregnancy and the contraction and retraction of the middle zone in labor, there will be more or less hemorrhage.

If the placenta be implanted wholly above the ring of Bandl we will have a safe insertion, a truly lateral implantation of the placenta, but not previa. When the ovum becomes attached to the fundus of the uterus, the placental attachment becomes fundal, but owing to the anatomical relation of the tubes to the cavity of the uterus and the influence of gravity in determining the implantation of the ovum, I regard the fundal implantation of the placenta as very rare.

The normal attachment of the placenta, in my estimation, is that portion of the uterus, which afterwards becomes the middle segment or equatorial zone.

In the early months of pregnancy the area of implantation is very small; the lower uterine segment very short; hence for a while at least, the placenta will develop in conformity with the growth of that portion of the uterus to which the placenta is attached. With the advance of pregnancy, however, the anatomical changes above described take place in the lower uterine segment. The uterine wall above becomes thicker and prepared for contraction; below it becomes thinner, and this portion of the uterus expands. The placenta, if attached to the lower zone, will, for a while, at least, participate in the changes that take place in the wall of the uterus; thus: first, there will be an enlargement at the seat of attachment, then as the lower uterine segment becomes distended the placenta also expands. Finally the limit of expansion is reached, and then one of two things must happen; either, if the insertion upon the uterine wall be unusually firm or extensive, partial rupture of the placental tissue takes place, or, which is more common, separation of the placenta from its base, results. In either case there will be hemorrhage, and we thus have the explanation of this cardinal symptom of pregnancy.

Liability of Physicians in Cases of Malpractice.

BY CLAUDE S. WILSON, A. B., LL. B.,

Professor of Medical Jurisprudence in the Nebraska College of Medicine.
Lincoln, Neb.

In this day and age, when unscrupulous persons are longing for an opportunity to recover damages from every possible source, on almost any pretext, as an easy way of getting along in the world, it behooves the man of responsibility to fortify himself against such attacks. Statistics show that at the present time damage suits make up a large proportion of the litigation with which our courts are compelled to deal. No doubt some of these cases have merit, but many more are instituted with the end in view of securing a settlement, or, if finally tried, that the tender-hearted jury will reward the efforts of the plaintiff sufficiently to make the attempt worth while. In nine cases out of ten the plaintiff secures the services of counsel upon the understanding that the attorney shall be paid only out of the recovery, and as the latter is out nothing but his time, he has little to lose and may, perhaps, gain a large fee. Aside from the corporations, which to many seem to be a legitimate object of prey, the physician perhaps stands forth as the greatest attraction for these thorns in the side of humanity. Many a practitioner, when he attempts to collect a bill for services rendered, is confronted with the information that the treatment or operation has not been successful, but, on the other hand, absolutely detrimental, and that he or she is contemplating bringing action for damages by reason thereof. In many instances the intention of bringing the damage suit did not arise in the mind of the patient until he had been pressed to pay the past due claim. And many of them take this means of discharging a just indebtedness. Realizing that a damage suit is annoying, if nothing more, many physicians will drop the matter and cease to press the collection of the account, rather than have any further difficulty with it.

It is a difficult matter to put a stop to such practices, and so long as the spirit of graft predominates just so long will the physician be confronted with such obstacles.

In this article I wish to call the attention of the physician to a few things which in the future it may pay him to remember. Many people are of the opinion that a physician must treat any patient who applies to him for assistance. This is not true, for the physician may, like the lawyer, refuse any case. "Wharton on Negligence," Section 731, in speaking of the rights and liabilities of the physician, says: "No question can exist as to the legal right of the physician, unless he be an officer of the Government charged with specific duties which he thereby violates, to decline to take charge of the particular case." On the other hand, once having

accepted a case the law at once sets in operation certain implied duties on the part of the physician, failure or neglect of which will render liable in civil damages to the patient. A physician who undertakes to treat a case contracts with the patient, impliedly under the law, that he possesses ordinary skill and experience. Also that he will use, in the treatment of the case, a reasonable degree of diligence. Relative to the first point, it might be stated that it is difficult to determine just what constitutes ordinary skill. It can not be measured by any fixed rule, is not a question of law, but one for a jury to decide from the evidence produced at the trial. It is evident that the law demands greater skill from a physician practising in a metropolis than from one who confines his work to a village. The law recognizes the advantage which large cities offer in the way of hospital facilities, experience, etc., and increases the burdens of those physicians who are able to enjoy the same.

As suggested above, not only does the physician who undertakes to treat a case contract with the patient, under the law, that he possesses reasonable skill and experience, but he also impliedly agrees to use all care and diligence in the entire treatment of the case; the bandaging, the dressing, the diet, must all be looked after, and to neglect any part of the same may cause the patient serious trouble and perhaps death. Such carelessness on the part of the physician will not be excused, and he will be held for any damages suffered by his patient by reason thereof. Under the law a physician or surgeon, in undertaking to treat a case, does not become an insurer or guarantor to cure. The law says he must do the best he can, and if he does his duty and bad results follow he can not be made to answer for any damages. Should, however, the physician be so foolish as to enter into a contract in which he agrees to cure his patient, the law will hold him strictly to it, and a failure on his part will make him answerable in damages. In such case he will not be permitted to plead unforeseen contingencies, for the law supposes he took all such things into consideration at the time the contract was made.

Some people are of the opinion that gratuitous service on the part of the physician will exempt him from damages, but such is not the case. It makes no difference whether the patient expects to pay or whether the physician does not intend to charge for his services, the law places upon the latter the same duties, and his failure to fulfill the same renders him liable.

In a recent case the physician took with him in a confinement case a young, unmarried man, who was neither a physician nor a student. This fact was not made known to the family of the patient until afterwards. A suit for damages was brought against both the physician and the attendant, and a verdict rendered against both. Medical men can not be too careful in such cases. Clearly they have no right to humiliate their patients, as did the physician in the case stated above.

A frequent cause for damages is the failure of the physician to reduce dislocations. In many instances the difficulty grows out of the fact that the medical man has not discovered the extent of the injury sustained. More frequently, however, the extent of the injury is discovered, but a dispute arises as to whether or not the physician has accomplished the attempted relief. In such cases this question arises, what degree of skill must the physician possess, or what amount of diligence must he use in order to escape liability? To say that he must exercise the greatest degree of care or possess the highest degree of skill, would certainly be unjust to him. On the other hand, to say that he need use only that amount of skill or exercise that degree of diligence possessed by moderately-educated members of the profession, would be unjust to the public. The law attempts to strike a happy medium between these two extremes. In discussing this, the Supreme Court of Iowa, in the case of Smothers vs. Hanks, 34 Iowa, 286, takes the view adopted by the weight of authorities. In that case the court holds that the physician, to escape liability, must possess that amount of skill and use that degree of care which the profession, as a whole, exercises. In determining the skill of the physician, due regard must be had for

the school of medicine to which he belongs. He must be measured by the standard of his own school, and not by any other.

The physician should also remember that, having undertaken to treat a case, he is in duty bound to continue so to do, and should he improperly discontinue his services he would be liable for any damage which the patient might suffer. By this I do not mean that the physician must continue to treat every case which he undertakes, but should he desire to quit the case he must give the patient reasonable notice, and permit him to secure another physician, in order that he may have the benefit of medical services continually.

Very often the physician will desire to perform an autopsy, but it should be borne in mind that he has no right to do this without the consent of the next of kin. In the case of the husband's death, the wife should be consulted. In the case of the death of the wife, the husband's consent must be had before the autopsy can be held. If the deceased person has neither husband nor wife then the next of kin has the right to pass upon this subject. The authorities are quite clear on the proposition that the next of kin have the right to immediate possession of the body, and that it must be delivered to them in the identical state in which it was when breath left it. There is an exception to this rule, however, and that is in cases where the patient dies under suspicious circumstances. The Coroner, in such cases, has a right to hold a *post-mortem* examination to ascertain the cause of death.

In this article we have been discussing some of the various cases in which the physician might be made to answer in damages. In conclusion, let me explain the kind or measure of damages. Legal authorities generally divide the subject into three heads, viz., nominal, compensatory and exemplary damages. Nominal damages are awarded when some duty of the physician has been neglected, but no serious loss sustained. Compensatory damages mean just what the term indicates, a damage to compensate the injured party for the loss suffered. Exemplary damages go further than the real loss sustained. In most States the courts frown upon exemplary damages, and limit the injured party to nominal or compensatory redress.

[Written for the MEDICAL BRIEF.]

An Observation on Numbers of Bacteria in School Rooms.

BY L. S. ROSS, M. SC.,

Professor of Biology Drake University; Director of the Des Moines Auxiliary State Bacteriological Laboratory.
Des Moines, Iowa.

At the request of the President of the Polk County Medical Society, in November, 1905, I made a little investigation into the bacteriological conditions of the school buildings of Des Moines.

Because of circumstances, the work was hurriedly undertaken, and because of that fact, was more crudely done than it otherwise would have been. Not having apparatus available for the determination of the number of bacteria in a measured quantity of air, and not having time to prepare such apparatus, it was necessary that the method adopted should be the rather crude one of exposing Petri dishes in the air of the school rooms for a definite period of time. It was also necessary that these dishes, while being exposed, could not be under direct observation; consequently I do not know that in all instances they were all undisturbed, although I believe such to have been the case. For these reasons, then, you will readily understand that results obtained can be considered only as approximate instead of being scientifically accurate. For a period of thirty minutes a Petri dish containing ordinary gelatine medium was exposed in each building, in the room which was most crowded with pupils. At the beginning of the exposure of the dishes in the rooms selected for the purpose, the teachers gave the pupils a marching drill, or calisthenics—with one exception, that being in the case of the room in the West Side High School, in which the request was not made—in order that the dust of the room should be put into circulation. Teachers were requested to replace the covers on the

dishes at the end of the allotted time and take them to the principal's office.

Upon the return of the gelatine dishes to the laboratory, they were placed in the incubator room and kept at room temperature for a period of forty-eight hours, with the exception of some of the dishes, which unavoidably were permitted to stand sixty hours before the count of the colonies was taken. If the dishes had been permitted to incubate longer, the probability is that a larger number of colonies would have developed. As has already been stated, the determination of number per cubic meter could not be made by the method employed. The number of colonies on the gelatine plates exposed in the different buildings is as follows:

Benton, Room 1	1,150
Bryant, Room 10	504
Curtis, Room 5	903
Bremer, Room 1	875
Emerson, Room 5	1,320
E. High Assembly Room	386
E. High Toilet, girls	478
Lucas, Room 4	784
Webster, Room 8	435
Longfellow, Basement	695
Longfellow, Room 1	415

This makes a list of buildings in East Des Moines in which dishes were exposed.

The number of colonies on the plates exposed in the different buildings in West Des Moines is as follows:

Franklin, Room 7	353
Irving, Room 5	253
Bird, Room 5	323
West High, Room 11	93
Lincoln, Room 2	460
Summit, Room 3	235
Forest	355

The incubation period in the following buildings was sixty hours instead of forty-eight.

McKinley, Room 2	325
Washington, Room 8	615
Oakland, Room 10	425
Garfield, Room 4	151
Crocker, Assembly Room	198
N. High, Troutner Room	129

Leaving Room No. 11 of the High School out of the calculation, the average number of colonies per dish exposed in the West Side buildings was 322; in the East Side buildings, 677. With these counts as a basis, I find that just after the dust of the rooms is put into circulation by the children marching, the bacteria fell to the floor at the rate of 7,403 on one square foot of floor surface in one hour of time in the West Side buildings, and at the rate of 15,570 on the same area in the same time in East Side buildings. Considerable variation in numbers is noticeable in different buildings, the smallest number in any West Side building being 129 and the largest 615. In the East Side buildings the corresponding numbers are 375 and 1,320. Of course, conditions of exposure of the dishes could not be identical in the various buildings. The location of the building affects, in considerable degree, the number of germs in the air. The fact that conditions under which the dishes were exposed could not be identical makes it evident at once that the number of colonies in the different buildings is not to be taken as an exact measure of the efficiency of the janitor service in the various buildings. Yet it does indicate with a greater or less degree of accuracy the relative condition of the rooms at the time when the exposures were made. The number of colonies developing in the dishes exposed in the East Side buildings is approximately two times the number developing on the West Side. I attribute this difference to a great extent to the fact that the floors of the West Side buildings were kept oiled with a special preparation to prevent the dust rising, while those on the East Side were not. Bacteria are heavier than air, and consequently tend to fall to the ground or floor. If the surface of the floor is such that the dust and the bacteria adhere, then movement in the room, as a natural consequence, will fail to put much of the dust into circulation. No better illustration of the sticking of dust to an adhesive surface can be given than John Tyndall's classic experiment in 1876. If the surface of the floor is moist, then the bacteria will adhere. So long as the dust and bacteria are moist they will not be taken up to any very great extent from the surface by ordinary air currents. It has been known for a number of years that the air in sewers is much more nearly pure bacteriologically than is the air in the street. It is not necessary to state that in order to keep the air in the school room as nearly free from bacteria as possible, the floor, the walls and furniture must be kept as thoroughly cleansed from dust as practicable.

1308 Twenty-Fourth Street.

[Written for the MEDICAL BRIEF.]

A Few Words on Diet in Tuberculosis.

BY W. W. BUTMAN, M. D.,

Professor of Theory and Practice of Medicine in the Denver Homeopathic Medical College. Denver, Colo.

We all know the marked effect of a well-cooked meal, carefully prepared and attractive in appearance. To the tubercular patient whose digestion is usually more or less impaired, whose appetite is poor, how much more important is a proper selection of foods. I may say almost, how imperative; for no matter what our medication may be, our best efforts in this direction will be frustrated unless the patient's diet is carefully looked after.

It is needless to say that no routine of diet can be prescribed for tuberculous patients. The patient must be given the food which is best for him, and at the same time food which he cares for. It is worse than useless to force feeding to the point of nausea. One may say that this is never done. I know otherwise, however, and have seen patients fed on a diet of milk and eggs until the appetite of the patients were entirely gone, and the digestive apparatus completely upset. No better diet could be recommended than the foods above mentioned, but if the patient does not care for milk and eggs, and they do not agree with him, nothing is gained by forcing him to eat.

I do not believe in limiting a tubercular patient to one or two or three articles of diet; no matter how excellent and nourishing these may be. It must be remembered that the patient's entire system is in need of repair, and it is absolutely necessary that he should have all the elements of repair in all forms of food. The patient must eat whatever agrees with him, and if this particular diet is that best adapted to his condition, he is fortunate. It is very easy for the physician to recommend a certain amount of nitrogenous food; a certain amount of albuminous, etc., etc., but he should also be sure that the patient is able to secure a good quality of these foods, and their proper preparation. But a small proportion of tubercular patients live in hospitals or institutions where the sick diet question is understood and properly carried out. Foods that would be most attractive and palatable, and easily digested when prepared by those skillful in such work, may become exactly the opposite under other circumstances. It is wise, therefore, for the physician before prescribing such diet to investigate sufficiently the patient's mode of life, to know whether his orders can be carried out. To the patient living in a boarding house, for instance, or a farm house, how utterly impossible it is for him to secure such a common article of sick diet as beef tea. Properly made of the finest quality of beef it is one of the greatest aids in the diet of the sick. Made, as it is too often, of an inferior quality of meat, greasy, thick and unpleasantly suggestive of beef stew, it were much better omitted from the patient's dietary. This applies to many articles of food; unless they are properly prepared they had much better be omitted, and the wise physician will prescribe those foods which the patient can hope to have prepared in a fairly palatable form.

The diet, too, must be governed by the occupation of the patient. This latter governs also the time of eating. As a general rule it is better for the patient's system to eat more than three times a day, and a smaller quantity than the regular meal taken in health. If the patient's digestion is weak, feedings must be small in quantity and of greater frequency.

I do not believe in the use of alcoholic liquors to any degree in tubercular cases; believing that pure, unfermented grape juice is much more palatable, digestible and appetizing.

809 Fourteenth Street.

Inclosed is a one dollar "William," for which you may send the BRIEF to my address. The greatest objection that I have to it is that each issue contains so many practical and useful points. I have not the time to read them all.—T. B. GULLEFER, M. D., Greensburg, Ind.

[Written for the MEDICAL BRIEF.]

Some Experiences with the Different Methods of Treatment of Pneumonia.

BY A. W. RILEY, A. M., M. D.,

Professor of Principles and Practice of Medicine and Clinical Medicine in the Creighton Medical College; Physician to St. Joseph's Hospital, etc.
Omaha, Neb.

In almost all of my pneumonia cases I have used the salicylates, combined with expectorants, for the last five or six years. And at the present time I prefer this method of treatment in the very young and very aged cases. But in those patients varying from fifteen to seventy-five years of age I now use the quinine treatment with most satisfactory results. I have the deepest confidence in the latter method of treatment, and although I have used it in only fifteen cases as yet, every case, regardless of age, has recovered from the pneumonia itself; one patient only succumbing to complications after the pneumonia proper was cured. My method of treatment does not differ greatly from that laid down by Galbraith, and was first used by me after meeting Dr. Galbraith and hearing reports of other medical men who had visited his hospital and watched his patients from day to day.

Treatment is begun as soon as diagnosis is made, beginning with one drachm of quinine. In one hour the patient receives one-half drachm, then, in two hours, twenty grains, and after that ordinarily but six grains every three hours. Following this treatment, temperature usually disappears in twenty-four hours. If, after two or three days, however, there should be a noticeable rise of temperature, one-half drachm of the quinine is administered instead of the six-grain dose, the six grains continued as before. After the first day the temperature usually returns to normal, and the necessity for the larger dosage seldom arises.

The question may be asked: How is it possible to give such a large dose of quinine, or, rather, how to get the patient to take it without complaint? My method is to rub the quinine up with syr. yerba santa and glycyrrhiza, making a paste, adding a little water to hold it in suspension. In this form the patient usually makes no objection; and, in fact, rarely speaks of the bitter taste. If one dose is rejected, it can be repeated, and he rarely rejects the second.

In cases complicated by pleurisy, contrary to the usual custom, I make it a practice to give sulphate of morphia to relieve pain, and expectorants when necessary to secure relief from annoying cough. I believe when pain is present, or any symptom which interferes with the rest and comfort of the patient, it should be relieved, when possible.

Under the quinine treatment I have not found the usual heart stimulants necessary; the drug itself apparently acting as a stimulant. It seems to have a tonic effect on the heart, and its influence upon peripheral circulation is decidedly marked. The patients are invariably ruddy in color, and there is every evidence that the blood is driven to the surface of the body, thereby relieving the congestion of the internal organs.

Another merit of this method of treatment is that it does not interfere with the nourishment of the patient. I have been in the habit of giving some preparation of meat juice, alternately with milk, every three hours, but after the temperature goes down to normal the patient will require more nourishment, and can be given something else.

Objection has been made by those who do not favor this treatment that it is followed by violent delirium. In reply to this I can only say that I have seen violent delirum in many pneumonia patients treated by the salicylate and other methods, and I am convinced that quinine is a most valuable remedy in almost all cases of pneumonia. And right here I wish to speak of this treatment in a recent hospital case. A young man who had been operated upon for appendicitis developed pneumonia in forty-eight hours; becoming delirious, he escaped from the nurse, leaped from the window, and was found and returned to the hospital some hours later. He was put on the quinine treatment, and the following day, while his right lung was completely consolidated, he appeared well and ready to take

nourishment, and remained in that condition until the lung was entirely cleared up. Every physical sign of pneumonia was present in this case prior to the dosage of quinine.

In my private cases I always discuss this method of treatment with the patient or his family, and am governed by his or their preference; assurance, however, being given that I have seen no bad results following the quinine dosage.

A medical authority stated some time ago that "pneumonia was the old man's friend," since it appeared usually at a time when he had outlived his usefulness, and it was pretty sure to carry him away. Although we were formerly taught to expect a fatal outcome in aged patients suffering from pneumonia, I would like to mention a recovery in a patient eighty-seven years of age. And two more recent recoveries in patients seventy-four and seventy-eight years, respectively. In the first-mentioned case the salicylate method of treatment was used. The quinine method has been used, and has given me good results in patients ranging in age from fifteen to seventy-five years.

The Diagnosis and Treatment of Iritis.

BY H. H. LEAVITT, A. M., M. D.,

Professor of Ophthalmology in the College of Homeopathic Medicine and Surgery of the University of Minnesota.
Minneapolis, Minn.

One of the common diseases of the eye, one fraught with great danger to the usefulness of the eye as a visual organ, is usually seen first, diagnosed and treated by the general practitioner. It too often happens that the case is referred to a specialist only after alarming complications have intervened. Such is the role of iritis in the great majority of cases. It is important, therefore, that the general practitioner should be familiar with the important features of this disease.

The iris is a curtain which hangs in front of the lens, and is attached at its circumference to the ciliary processes a little in front of the corneo-scleral juncture; it is pushed slightly forward towards its center by the lens; the central portion is lacking, however, thus forming a pupil; posteriorly it is covered by the pigment layer of the retina; it is well supplied with blood vessels, most of which run in a radial direction. These branch from an artery lying around the outer margin of the iris which is called the large circular artery of the iris. Near the margin of the pupil there is another artery, also circular, which is called the small circular artery of the iris. The large circular artery is supplied with blood from the long ciliary arteries which anastomose with the ciliary arteries from the blood vessels in the conjunctiva. Around the inner margin of the pupil is a muscle about a millimeter in width; the sphincter pupillæ. This muscle is supplied with a branch from the third nerve.

The symptoms of inflammation of the iris are very characteristic. The subjective symptoms are pain, photophobia and impaired vision. The pain is of a peculiar character, neuralgic in type, and is frequently so severe as to make sleep impossible. The objective symptoms are change in the color of the iris, being generally darker, owing to the congested condition of the blood vessels with which the iris is so plentifully supplied. The pupil is somewhat smaller than the pupil of the other eye, as a rule, and the aqueous humor is apt to be cloudy, so that the pupil loses its blackness. If an effort is made to dilate the pupil more or less adhesions will be seen, so that the pupil will dilate irregularly. These adhesions are known as synechiæ. In severe cases there is a deposit of pus in the lower part of the anterior chamber which is known as hypopyon. Frequently it is tinged with blood—a condition designated as hyphemia.

If the vision is tested at this time it will be found to be very much below the normal. The condition of the ciliary vessels at the margin of the iris is also of value in making a diagnosis from conjunctivitis, the congestion diminishing as the distance increases from the ciliary margin. In conjunctivitis the blood vessels are more easily made out; the redness is apt to increase rather than diminish at a distance from the ciliary margin.

About fifty per cent of the cases of iritis are due to syphilis, rheumatism,

gonorrheal rheumatism, and other infectious diseases; traumatism making up a goodly number. The disease, if left to itself, is apt to run a course of three or four months and leave the eye much worse than before the attack. It is a disease that is very prone to recur. In the milder cases the most common sequelæ are synechiæ, which leave the iris attached to the anterior capsule of the lens at one or more points, and if the disease recurs we have additional points of attachment so that frequently the iris is attached to the lens all the way round the pupil, the anterior and posterior chambers are thus cut off from each other, and the excretion of the eye is thus interfered with. The tension of the eye is apt to be increased, and an attack of glaucoma supervene. Little spots are found deposited on the posterior portion of the cornea, and are apt to remain permanently, very materially interfering with the vision. It is common for an eye that is well on the road towards recovery to relapse and have a second attack of iritis; or, frequently the disease will attack the other eye. This tendency is readily understood when we consider the etiology.

Diagnosis. — The most characteristic points are the severe pain, the discoloration of the iris, the contracted pupil; turbid aqueous; the characteristic ciliary injection and the presence of synechiæ. The principal diseases with which it may be confused are glaucoma and conjunctivitis. In glaucoma there will be an increase of tension, usually a dilated pupil; the iris will be its normal color, and will dilate symmetrically upon the use of a few drops of cocaine. In glaucoma the pain is fully as severe, but less neuralgic in character; more of a grinding or boring pain. In conjunctivitis the pain is not so severe; seldom interferes with sleep; the secretion is more profuse and mucoid or mucopurulent in character.

The treatment should have reference to the causal indications. In the case of syphilis the remedy chosen should be one that will act quickly, and mercury still stands without a rival. It should be used preferably by inunction. If this is inexpedient, mercurial baths and internal medication should be substituted. Locally, atropin in a one per cent solution should be instilled into the eye every three hours, until dilatation is accomplished. If there are adhesions, it may be necessary to use atropin, pure, in the conjunctival sac, taking pains to compress the lachrymal sac while the salt is being dissolved to prevent its being carried into the nose, as it frequently causes systemic poisoning. As soon as dilatation is complete the use of atropin can be gradually diminished, once or twice daily being sufficient to maintain dilatation. In addition to this, the eye should be bathed fifteen minutes out of every hour with very hot water in which boracic acid or biborate of soda has been dissolved. The eye should then be covered with dry absorbent cotton to keep it warm, which aids very much in relieving the pain. If these means are not sufficient to dilate the pupil it is well to apply a couple of leeches well back on the temple, and it is a common occurrence to see a pupil that has long resisted other means begin at once to dilate. The treatment along these lines should be kept up until all pain and redness have disappeared from the eye, and the danger of a relapse has passed. When the disease is due to syphilis, it is advisable to follow up this treatment with the iodide of potash for several months so that future attacks in the same or in the other eye may be prevented. The patient should be cautioned not to use the eye too severely for some time after an attack, as the eye is a long time in regaining its normal strength.

Endometritis.

BY CHARLES J. DRUECK, M. D.,
Attending Surgeon to Lakeside Hospital, Rectal Surgeon to People's Hospital.
Chicago, Ill.

Endometritis, literally speaking, signifies inflammation of the lining membrane of the body of the uterus. Clinically, however, we seldom, if ever, find the pathology so limited; usually the trouble extends into the rest of the organ. That this is but the natural result is evident when we remember that the same nerves, blood ves-

sels and lymphatics serve all of the different structures, and all are alike subject to the various nervous and vasomotor changes. Infectious products picked up within the uterus are carried through the muscular body of the uterus to the minute network of lymphatics on the serosa, and then through the broad ligament.

Endometritis occurs in three classical forms. (1) Simple or hypertrophic, (2) puerperal or septic endometritis, and (3) tubercular endometritis. Each variety has its own history, symptoms and treatment so different from the others that each requires separate consideration. This paper has to do with the simple form, leaving the puerperal and tubercular infections for future consideration.

Inflammation of the endometrium is usually the reaction of the tissues to microbic invasion, but not necessarily so. Traumatism, suppressed menstruation, retained secretions, malposition of the uterus, morbid growths in or about the uterus and excessive venery and masturbation are all exciting causes, but such cases are rare. These same conditions are sometimes only predisposing factors, but when they are the sole etiology of the endometritis the symptoms are always subacute and mild in character, and never aggravated or severe, as occurs at times in microbic infections.

Normally, the cavity of the uterus is absolutely sterile, and the constant flow of mucus and lymph from the glands, although imperceptible in amount, is sufficient to prevent any of the micro-organisms usually found in the vagina from entering the uterus. Infection is, therefore, always mechanically introduced into the uterus through the use of unclean instruments, or manipulations, in the course of treatment, miscarriage, labor or the puerperium, or by the gonococci, which latter can develop, despite the lactic acid bacillus of Doederlein, which bacillus is normally found in the vagina.

The germs most frequently found invading the uterus are the gonococcus, streptococcus and staphylococcus. Others are ocasionally found, but they are of lesser importance.

Gonorrheal endometritis, sometimes called specific endometritis, is the most frequent form, and unless mixed with other germs, is subacute in character. It frequently spreads along the membrane to the fallopian tube, causing dire distress, but is rarely taken up by the lymphatics and carried into the general system. The gonococci are often aided by other germs (most frequently the staphylococci), and such combined infection is very virulent. In these instances, not only the toxins, but the micro-organisms themselves, may be taken up.

Endometritis due to infection by the streptococcus and staphylococcus (sometimes called septic endometritis), is a virulent infection, particularly that due to streptococci, and usually follows a miscarriage or confinement. This form of infection may occur in any degree. It is sometimes most virulent as well as far-reaching in its complications and sequelæ. The streptococci permeate all structures, the lymphatics, body of the uterus, ligaments, tubes and ovaries, and then out into the cellular tissue, causing cellulitis, and finally out into the peritoneum, producing peritonitis. In the worst cases even entering the general circulation, causing septicemia. In this septic form the mucosa sloughs off, or occasionally is covered with a diphtheroid deposit. This destruction usually occurs in patches, but may be diffuse, and large pieces of mucosa, or even the muscle wall of the uterus, is cast off.

Simple endometritis presents many variations in character and course, according as the parenchymatous or interstitial structures are involved. Where the glandular structures are chiefly affected, they tend to fill the cavity of the uterus and block up the cervical canal. The secretion is abundant, and is retained until decomposed, and the odor very offensive and suggestive of malignancy. This condition is sometimes called benign adenoma. In other cases both the glandular and interstitial tissues are hypertrophied, and a fungoid condition develops.

Each of these conditions is but a different form of the same disease, *i. e.*, hypertrophic endometritis, and in the later stages, when the endometrium is thin and the elements obliterated, it is called atrophic endometritis. This is the condition found in hyperinvolution following pregnancy, in old age, and in the late stages of

chronic localized inflammation. In the late (atrophic) stage, the discharge may be abundant, but it contains few lymphoid elements, hemorrhage is scant, and the blood tends to coagulate because of the lack of lymph. Dysmenorrhea and supersensitiveness of the uterine canal occur. In the aged the endometrium is sometimes entirely missing and the muscle atrophied. The discharge is thin and purulent; sometimes bloody and erodes the vaginal and vulvar surfaces. These different stages are never sharply defined, and every patient presents symptoms of several stages. Therefore a classification based upon the clinical picture as catarrhal, hemorrhagic or senile is ambiguous and confusing, and should be abandoned.

The symptoms of endometritis are pain, increased secretion, menorrhagia or metrorrhagia, fever and reflex nervous manifestations of various kinds. In a mild case, with the disturbance limited largely to the endometrium, these symptoms are mild or indefinite, and a diagnosis may be doubtful. Likewise, if uterine, tubal or ovarian disease complicate, the symptoms may be so masked as to render only an obscure picture.

The pain of endometritis is a constant, dull ache in either the uterus or the region of the lumbar plexus; sometimes radiating through the pelvis and thighs. When obstruction of the cervical canal exists, or there is flexion of the neck, the pain is spasmodic, and if the peritoneum is involved the pain is lancinating. As these same nerves are affected in all pelvic disturbances, this same character of pain is complained of in each and every affection, and is not pathognomonic of endometritis.

The secretions are increased in quantity; thin, and either purulent or bloody. It decomposes so quickly, and has such a decayed flesh odor that an erroneous diagnosis of malignant disease is sometimes made. These discharges destroy the spermatozoa, and the women are usually sterile, or, if conception occurs, the endometrium furnishes but poor support to the ovum, and abortion usually occurs early.

Menstruation is promptly affected. It is frequently suppressed for a time, and in septic endometritis may not reappear. The suppression of lochia or menstruation always betokens serious infection. Menorrhagia and metrorrhagia usually supervene. In chronic endometritis the menstruation is more profuse, and the period protracted. Frequently it amounts to a menorrhagia. There is also sometimes a hemorrhage between the usual menstruation.

Fever is slight, except in the acute cases, when it may be high (104° to 105° F.), and is accompanied by frequent chills.

Among the reflex phenomena are vortex or occipital headache, irritation of the bladder and rectum, nausea and attacks of hysteria, melancholia or neurasthenia. The patient soon becomes anemic and weak. All of these symptoms are aggravated by conditions that determine a venous congestion to the parts; such as long standing or long walks; constipation and the menstrual periods. All of the subjective symptoms seem out of proportion to the local pathological findings.

Examination.—Examination shows the cervix edematous, and frequently eroded and granular. The uterus is large, boggy and tender. A thick glue-like discharge escapes from the os, but if this is wiped away the characteristic thin, bloody or purulent discharge from the uterus will be seen. The cervical canal is partly open. Depending upon which part of the organ is involved, the cervix may not be appreciably affected, or the uterus may be hard, of normal size and not tender. In the late (atrophic) stage of the hypertrophic endometritis the uterus may be diminished in size and the discharge clear.

Examination with the uterine sound determines a patulous cervix, and a very sensitive corporeal endometrium. Such an examination is very painful, and is followed by bleeding, because of the fragile blood vessels.

Diagnosis.—The distinguishing signs and symptoms of endometritis are dull pelvic ache, enlarged, tender uterus, open cervical canal, thin purulent or bloody discharge from the cervix and the sensitive bleeding lining of the uterus.

Microscopical examination of the scrapings of the uterus are sometimes necessary to differentiate the various forms of endometritis or to exclude other lesions. Such a curettage (exploratory curettage) can usually be accomplished without an

anesthetic, because of the patulous cervical canal.

Treatment.—In simple endometritis rest in bed, saline laxatives; a plain, absorbable diet, hot sitz baths and hot vaginal douches of plain water or normal salt solution are all that is needed. When the disease is complicated with other disturbances of the uterus or adnexa, of course, they need attention primarily.

Malpositions, flexures, deformities or stenoses of the cervical canal, or a lacerated cervix, must be remedied. Retained placenta, polypi or morbid growths within the uterus may be the exciting cause, and perpetuate the endometritis until they are removed. In the non-septic cases local treatment should be deferred until the acute stage, with pain and tenderness, has passed, unless there is some positive indication for special treatment. In the specific cases curettage is always indicated.

In the septic forms with continued fever it is necessary to douche repeatedly, and these douches should be performed under the strictest aseptic precautions. When intrauterine douches are given the return flow must be watched, because there must be unimpeded exit. Usually the cervical canal is patulous enough to allow a ready return flow, but if it is not a return flow douche must be used. Serious and even fatal accidents have occurred because of neglect of this precaution.

The germicidal property of the douche is of less importance than the flushing effect, and sterile water or normal salt solution will act very well when used every three to six hours. The stronger antiseptics may be indicated in special instances (bichloride 1 to 5,000 or carbolic acid one per cent), but they must be used less frequently, because a portion of the solution is left within the uterus, and when this is absorbed there is always the possibility of systemic poisoning.

All infections consume the patient's vitality, and in these protracted and virulent poisonings it is well to urge a simple but highly nutritious diet. Alcohol, ammonia and other stimulants are considered only as the indication arises, but iron, quinine and strychnine are useful in all cases as general tonics. Any constitutional dyscrasia should also receive attention.

When the temperature is high an ice-bag over the hypogastrium is soothing, and reduces the temperature, but it must be removed as soon as the temperature falls.

After the acute stage has passed, constitutional measures are of much importance. Absolute sexual rest, a carefully regulated diet, close attention that the bowels are loose or free; regulation of the hours of work and exercise so that the patient is not fatigued by prolonged standing or walking. Comfortable but loose-fitting clothing, plenty of fresh air and sunlight and a change of scenery.

General therapeutics are more important in chronic cases than the local treatment, although each case presents its own peculiarities.

In simple endometritis (that due to other uterine disturbances), the underlying cause will, of course, need first attention, because, while much may be accomplished by local treatment the benefit can be but temporary if the exciting cause remains. After subinvolution of the uterus, laceration of the cervix or perineum or displacement of the uterus has been remedied, the patient's recovery will be hastened by the vaginal douches, applications of iodine, ammonium-sulpho-ichthyolate and glycerin to the vaginal vault or puncture of the cervix as indicated.

When this treatment has been followed out and fails to give relief, recourse to the curette must be had. The operation of currettage will be taken up at another time. Applications to the endometrium are both useless and dangerous, and can not be considered.

Abortion—An Ethical View.

BY WM. WHELAN,

Professor of Medical Jurisprudence in the John A. Creighton Medical College.
Omaha, Neb.

It is strange that in these days of advanced science and improved methods there still lingers in the minds of some otherwise eminent in the medical profession the conviction that in extreme cases

of pregnancy they are masters of life and death.

The fact that it is the commonly accepted theory that, when conception takes place, there is life, precludes any excuse for destroying the fetus' life in the early stages of gestation. But whence have these practitioners obtained the right they boldly claim to possess? Surely they have not received it from the author of life—God. God says: "Thou shalt not kill." Nor has the State given them the right, because the State herself can not take away an innocent life. We all admit that the State may lawfully wield the sword in a just war, and may inflict the death penalty on those guilty of great crimes, but she is never allowed to sacrifice an innocent life for any purpose whatever. If the State has not the right to do away with an innocent life, much less has the individual. Self defense against an unjust aggressor can not be urged as an exception to this rule, which regards innocent and not unjust persons. There is, moreover, in this case of the fetus *in utero*, no question of the plea of unjust aggression, for if there be any aggression it is not the fetus that is the aggressor towards the mother, but rather the mother towards the fetus. The fetus has done nothing to constitute itself a menace to the mother's life, hence there can be no question of an unjust attack.. Furthermore, does not the obstacle to delivery lie with the mother? If, then, through an act of the mother's will, the fetus has, without its co-operation, been placed in the mother's womb or lodged outside of the womb, as is the case in ectopic gestation, can the child or fetus be called an unjust aggressor, or an aggressor at all?

Besides this plea of unjust aggression, those who claim they have the right to dispose of the life of the fetus tell us that the value of the fetus' life is nothing in comparison with that of the mother, that the fetus is doomed to die, and at all events it is better to save one life than allow two to perish. Such an argument comes from the heart, and not from the head. We are dealing with principle, not sentiment. If the physician acts through sentiment, and not from principle; if he so justifies his conduct, what will be the result if he carries such a principle to its logical conclusion? The asylums for the hopelessly insane and the houses for incurables scattered broadcast throughout the land, and giving evidence of our care and regard for these afflicted of humanity should, in the logic of such practitioners, be done away with, because the inmates are doomed, and their lives are worthless; rather, there would be no need for such retreats because there would be none to occupy them. But the defenders of the right to dispose of the doomed will say that such a right is restricted to the child *in utero*. Is there any material difference between the child *in utero* and the child on its mother's lap? The right of each to live is sacred, and as inviolable as that of the mother, and whatever plea or excuse is offered by those who disregard this inalienable right to life must be considered as emanating from such as sacrifice obligation to expediency.

It would seem, then, that the physician or doctor is never allowed to procure an abortion. Before we answer this query, there is need of a distinction. An abortion that is procured directly, namely, such an abortion that is a direct killing of the fetus, or one in which the fetus is the direct object of operation, or of any other method of procedure, is never allowed. If, for example, the pregnant mother is suffering from uncontrollable vomiting, which the practitioner knows he can stop by applying an electric current to the fetus, he is certainly making the fetus the direct object of the operation, and if death ensue, he is guilty of a direct killing of the fetus. This would be a case of procuring abortion directly, and a serious violation of the natural law.

We may suppose another case. A pregnant uterus is cancerous, and we will take for granted that the removal of the uterus is a necessary condition of the mother's life. What is the physician to do? The moral view should at all times determine his position, and it is this: He does not wish to procure an abortion; on the contrary, he will try his best to prevent it. He will not directly attack the life of the fetus; he operates and removes the womb; but in the operation he does not make the fetus the direct object of attack, though he knows the fetus

in the womb removed will not long survive. This is procuring abortion indirectly, and is admitted by moralists under the following conditions:

A cause is placed that has two effects, one good, as in the case just given, the saving of the mother's life; and the other an evil effect—the indirect destruction of the fetus; the evil effect is not willed, all reasonable effort is made to avoid it; the immediate effect desired is the saving of the mother's life, and is good in itself; the good effect intended is as important as the evil effect permitted, and finally the evil effect—the indirect destruction of the fetus is not made a means to obtain the good effect—the saving of the mother's life. We may then, in extreme cases, give such medicine or perform such operations as will act on the mother's system or on her organs to save her life, and permit the sad effect, which will indirectly affect the child; but we may not injure the child directly, as this would be using a bad means to obtain a good end—the end never justifies the means. So, too, with ectopic gestation. The same principles apply to both intra-uterine and extra-uterine gestation. The arguments for one are the same as for the other. In a case of ectopic gestation, the growth may be diagnosed as a tumor. If there is no immediate danger, the duty of the physician is to wait for development. It may be a tumor; it may be a living fetus. If it proves to be a child, no operation is permissible before the period of viability. Suppose, however, that it cannot be diagnosed as a fetus, and yet it is threatening the mother's life, what is to be done? It may be removed, as was the cancerous womb in intra-uterine gestation. It follows, then, from the natural law that in an extreme case, as in the cancerous womb, the removal of which is absolutely necessary to save the mother's life, abortion may be procured indirectly, or, rather, to speak more strictly, indirect abortion may be permitted; otherwise nothing may be attempted before the fetus is viable. When the period of viability is reached, in case of need, premature labor may be induced, the Cæsarian section, the Porro operation, or laporotomy may be performed.

If the principles of the natural law were made the subject of closer study by the profession, this crime of abortion would be considerably decreased, and in consequence we would have brighter and happier homes.

[Written for the MEDICAL BRIEF.]

Diet in Health and Disease.

BY W. A. GEORGE, B. S., M. D.,

Professor of Dietetics and Hydrotherapeutics in the Nebraska College of Medicine; Superintendent of the Nebraska Sanitarium. College View, Neb.

The importance of proper diet cannot be over-estimated, as every function of the body depends upon proper material for building up the organs, and where improper material is used we can expect evil results.

A food is said to be any substance which repairs waste of the tissues, and produces heat and energy. That is, some foods only repair waste, while others only produce heat and energy; the perfect food must include both.

Six food elements may be mentioned: The first, not commonly called a food, is of the greatest importance; we refer to oxygen, which is the only food element that is also a chemical element. We all recognize that oxygen must be received continually, and this emphasizes the importance of proper ventilation, both in health and disease, and especially in disease where the breaking down processes are more rapid than in health.

The next food element is also usually not included among the foods. We refer to water. Water makes up from three-fourths to four-fifths of the tissues of the body, and as it is continually being given off, must be replaced by a liberal supply. Nearly all foods, even those in dry form, contain some water; but water should be taken freely, as most people do not drink enough, especially those living sedentary lives. This is a common cause of constipation. It is better not to drink at meals, but to drink freely, beginning one or two hours after eating. In cases of dilated stomach, and in some cases of poor digestion, the food taken should be dry, as water dilutes the gastric juice, as

well as the saliva, and thus prevents the proper action of these juices.

Of the remaining four food elements albumen may be said to be the most important. It is a perfect food, because it will both build up the tissues and produce heat and energy. All of our foods should contain enough of this element, and yet recent experiments have shown that much less albumen is required than was supposed by students of physiology a few years ago.

Next in importance are the carbo-hydrates, including the various kinds of sugar, starch, dextrine and cellulose. The sugars require no preparation for digestion, although cane sugar must be inverted in order to be assimilated properly, and is, therefore, dangerous when taken in large quantities, as the digestive juices are unable to invert large quantities of this sugar into dextrose and levulose. In fact, it is better to use the other natural sugars, such as grape sugar, found in fruits, and malt sugar, rather than to use in considerable quantity the cane sugar.

The starches are the most important elements to consider in relation to proper cooking. A large proportion of nearly all our food is starch. Nearly all grains are made up of from two-thirds to three-fourths starch. When raw, starch is practically indigestible. In order to have the most perfect digestion starch should be mixed thoroughly with saliva, and the principal part of the digestion performed in the mouth.

Patients should be instructed to masticate their food very thoroughly, and this alone will often improve the digestion of the dyspeptic so that he will begin to improve at once. But if the starch is not thoroughly cooked the saliva will have little effect upon it, and it will be useless to tell the patient to masticate thoroughly. It is much better to have starchy foods in a form that will encourage thorough mastication. The best way to prepare this class of foods is by thorough baking, either in the form of crackers or some form of flake food. Zwieback is a very simple form of dextrinized food which can be prepared in any home. All that is necessary is to take an ordinary loaf of bread, cut into the usual slices and bake in an oven at a moderate temperature until they are browned clear through. This can be used in making most delicious breakfast toast by simply immersing the slices of zwieback in boiling hot water, and turning over the toast some dressing, such as hot fruit juice or hot milk or cream, or the zwieback can be eaten dry, and thoroughly masticated by those who need to eat dry food. It is also very nice when broken into soups.

We have no sympathy with the idea advanced by some today who are advocating raw foods. There is some question as to whether albumen is better taken raw or cooked. If albuminous foods, however, are thoroughly cooked in a form in which they can be masticated so that the gastric juice will readily mix with the particles of albumen, digestion will probably occur just as well as where taken raw. The gluten foods are an illustration of this. Wheat flour is mixed with water and washed rapidly until all, or nearly all, of the starch is removed, leaving a sticky mass of gluten. This, when thoroughly baked, either in the form of crackers or little biscuit, is ground into a fine meal, which may be eaten with milk or made into mush, and is very easily digested. It is one of the most valuable foods for diabetics who must take only small quantities of carbo-hydrates. In this case there is always some starch remaining, but by thorough baking, as we have just mentioned, the starch is well prepared as well as the gluten.

In the list of food elements we will place fats next. There is probably no food element which varies so much in quantity in all different foods, and perhaps no other element which can vary so much without affecting the nutrition. It is quite possible, as has been shown by different experimenters, that fats can be laid up in the body from either albumen or the carbohydrates, so that it is unnecessary to use fat in order to build up adipose tissue. It has also been proven that fat itself can be stored in the body as food, and in some cases large quantities of fat may be a very valuable adjunct to the food. It is very much better, however, to use fat in the form of an emulsion. For instance, cream would be preferable to butter. The fat found in nuts would be preferable to the vegetable oil. This is also true of the

fat found in the olive. These fats, when in their natural condition, are in the form of an emulsion, and are, therefore, ready to be assimilated directly into the blood and carried to the tissues, while, if taken in the free form, they must be emulsified.

Among the vegetable foods the largest quantities of fat are found in nuts. Many of the nuts are especially valuable in cases of diabetes on account of their being free from starch, and contain large quantities of albumen and emulsified fat. Among the most valuable nuts for this purpose are the English walnut, pecan and almond. Peanuts may be prepared in such a way as to make a valuable food, as they are rich in albumen and fat. They contain some starch, however, and are more like beans or peas; they need thorough cooking in order to be digestible. The ordinary method of roasting, however, is not good, as it has a tendency to produce changes in the fat, which are injurious.

The last of the food elements in our list includes the mineral salts. It is hardly necessary to say anything in regard to these salts, as they are found in sufficient quantities in the combination of other food elements. There has been considerable discussion in regard to the necessity of common salt in our foods. It is undoubtedly true that most people do better if some common salt is added to the food. However, no one has been able to prove by scientific experiments that large quantities of salt are necessary, and some have shown that very small quantities would be better for most cases. Salt, when taken in large quantities, is undoubtedly an irritant, and may produce bad results, especially in cases of kidney trouble.

Many patients need some simple instructions in regard to the combination of their foods, as bad combinations of good foods often produce more harmful results than the poor foods commonly used. One with a weak stomach will usually do better never to combine fruits and vegetables at the same meal. When this is done fermentation is likely to follow. It is better to eat fruits and grains at one meal and vegetables and grains at another, and better still to drop the vegetables for a time, and use only fruits and grains or seeds. All kinds of ripe seeds, including legumes and nuts, and all kinds of cereals, may be taken with fruit with good results. Some are ruining their digestive organs by using large quantities of milk and sugar. It is much better to discard the cane sugar and learn to use the milk without sugar.

A Few Suggestions to the General Practitioner.

BY C. W. KELLY, M. D., C. M.,

Professor of Descriptive and Surgical Anatomy in the Louisville Medical College; Dean of the Louisville Medical College.
Louisville, Ky.

Dislocations and fractures most commonly met in the upper part of the body, are those of the shoulder joint, fracture of the neck of the scapula, injury of the elbow joint, dislocation of the ulna backward, Colles' fracture, etc., etc.

Dislocation of the shoulder joint is extremely common, especially subcoracoid, and fracture of the neck of the humerus is frequently observed. Occasionally, also, we see fracture of the neck of the scapula, but very rarely of the anatomical neck. Fractures of the elbow are always serious. The displacement of the outer bone of the radius backward is common, as is also dislocation of the ulna backward, and fractures into the joint by the breaking of one of the condyles of the humerus.

The management of these conditions is not difficult. Dislocation of the shoulder is easily reduced; if subcoracoid, the arm is carried forward and backward; supinator and pronator elevation being simple.

Dislocation of the elbow joint of the lower bones backward can be reduced by bending the lower bones over the knee of the physician. Fractures near and into the elbow joint must be treated with great care to prevent deformity and immobility. I would suggest early movement of the joint after injury to promote the absorption of callus poured out into the olecranon and coronoid veins, and the doctor should be very careful in his prognosis of injuries of the elbow joint with fracture.

Colles' fracture, commonly known as the silver fork deformity, often occurs in old people, resulting from a fall on the

hand. It is a fracture of the radius above the wrist joint. It is managed by the application of a splint before and behind the radius, with a little padding between the bones, the ulna being elevated, and the hand a little bent down to overcome the contraction of the supinator longus muscle.

If these cases are properly managed there should be little or no deformity.

Some Practical Operative Suggestions in Hemorrhoidal Surgery.

BY A. LEIGHT MONROE, M. D.,

Professor of Materia Medica, Clinical Gynecology and Orificial Surgery in the Southwestern Homeopathic Medical College and Hospital; Dean of the Faculty. Louisville, Ky.

The operation most often available in ordinary hemorrhoidal cases is what is known as the "slit" operation, which, in brief, is as follows:

A short longitudinal slit is made in the distal end of the pile, care being taken not to injure its nutrient artery; through this slit the contents of the tumor can be easily curetted out by a blunt instrument. The slit can then be closed with one or two small catgut sutures. By treating one hemorrhoid at a time, in this way, the circuit of the gut is soon made. This operation is clean, simple, surgical, and almost free from any danger of future complications, as all the hemorrhage occurs at the time of operation and, therefore, under the operator's observation. The danger from blood-poisoning is almost *nil*, a matter of great importance when we consider the danger of septic infection after ligation or injection methods, and the possibility of hemorrhage following these methods when the slough separates, which hemorrhage occurs insidiously, and when the physician is not present to attend to it promptly. Preceding the slit operation the sphincter should be stretched pretty thoroughly, so as to prevent the painful contractions following such operations, but not sufficiently to paralyze its muscular power, as extreme dilatation tends to increase hemorrhage.

Where the tumors are large and there is much adventitious tissue, as in most cases of the chronic type, the clamp or cautery may be preferable. Most physicians are familiar with these operations, but as handwork is generally preferable to machine work in all the arts, so I prefer the American or the Whitehead operation, where they are available, and they nearly always are, in their simple form or various modifications; or one can do the American operation on one-half the gut, and the slit operation on the other half, in some cases. The American operation is almost a rectotomy, removing, as it does, the last inch of the rectal mucous membrane and the blood vessels underlying it. In this operation the diseased area may be exposed to view by being drawn down with four or five T forceps, and a circular incision is made at the junction of the diseased and varicose section with the healthy mucous membrane. This junction is indicated by a change in the color of the membrane from purple to pearl color. After the circular incision is made by the use of the forceps, the diseased inch may be inverted, exposing the underlying structures, consisting of connective tissue and varicose veins. These are easily snipped off with scissors, and the diseased mucous membrane amputated, and we have then exposed the lower inch of the rectum. By drawing down the mucous membrane which is still intact in the upper part of the rectum, and sewing it to the skin around the orifices, we supply a healthy membrane to the part. This is easily done, if too much mucous membrane has not been removed.

We have practically, then, a new rectum, and we have a radical operation, for it is rare that hemorrhoids ever recur after the American operation.

There are two dangers to be avoided. One is the possible injury of the sphincter; the other, that of poor coaptation, causing cicatricial tissue to form, which is such an obstruction as to cripple the action of the sphincter, causing total or partial incontinence; and, as a remote result, lawsuits, or what is equally as bad, injury to one's surgical reputation.

A practical experienced surgeon should be able to avoid these complications with care. As little of the membrane as possi-

ble should be removed, so as to avoid too great tension upon the stitches. This operation was first done by Dr. E. H. Pratt, of Chicago, and is a valuable contribution to rectal surgery. As most physicians already know, the Whitehead operation is exactly like the American, except that the incision, instead of being made above the internal sphincter, is made at the junction of the mucous membrane and skin at the lower edge of the external sphincter, and then as much of the mucous membrane as is palpably unfit to be retained is cut off before the parts are reunited.

I believe that all hemorrhoidal troubles can be cured by either the "slit," or the American operation, or a modification of them.

Diseases of the Breast.

BY ALFRED DE ROULET, B. S., M. D.,

Chicago, Ill.

Formerly Professor of Surgery and Diseases of Women in the Medical Department of Trinity University.

III. CHRONIC INFLAMMATIONS.

The chronic inflammatory diseases of the breast are naturally divided into two groups (*a*) those occurring in connection with or as a result of lactation, and (*b*) those developing entirely independently of lactation as the result of some specific infection. In the first class we would place the two principal forms of chronic lactation mastitis, *i. e.*, ductal mastitis and subacute or chronic mammary abscess. In the second group we would class the specific infections as tuberculosis and syphilis. In addition to these Warren includes in his excellent classification simple retention cyst and non-malignant eczema of the nipple and areola.

Chronic lactation mastitis occurs most frequently in young matrons as a result of infection of the milk ducts. In the ductal form of lactation mastitis, indurated masses appear in the breast. They are usually accompanied by considerable pain and tenderness, and are very likely to involve the skin. The axillary glands are usually enlarged. On section, numerous small abscesses and necrotic areas are found scattered through the breast in close relation with the larger ducts. Histologically there is a marked increase of connective tissue, while the tissues surrounding the ducts are the seat of a more or less pronounced round cell infiltration.

In a chronic or subacute abscess of the breast there is found a more or less irregular swelling of variable size, which has developed rather slowly, and which has not been accompanied by any appreciable pain or tenderness. Fluctuation may be elicited in some cases, but more often can not be detected. In cases of long standing the skin is not infrequently involved, and in such cases more or less pain and tenderness is present. The axillary nodes are usually enlarged.

The prognosis in chronic lactation mastitis is entirely favorable, if proper treatment is instituted. In the ductal form excision of the affected lobes is indicated, while in the chronic abscess simple incision and drainage is often sufficient, although in some instances excision of the lobes involved is necessary.

Tuberculosis of the breast is generally considered a very rare disease, but this reputation is, I believe, misleading, and not at all in accordance with actual facts. It is true that comparatively few cases have been reported, but that proves nothing. Secondary cases are often entirely overlooked, as they are not infrequently overshadowed by the gravity of the primary condition. For example, a case of mammary tuberculosis would, in all probability, pass unnoticed in a patient with advanced pulmonary tuberculosis. The primary cases in many instances are treated by the family physician as chronic mastitis, while not a few cases are undoubtedly operated by the enterprising surgeon for carcinoma.

The disease occurs most frequently between the twentieth and fortieth years, that is, during the period of greatest functional activity of the breast. Apparently there is no connection between the disease and lactation, although the majority of cases are reported in women who have borne children. The disease is usually limited to one breast, but occasionally both may be involved. As in cancer, the upper outer quadrant is affected more fre-

quently than any other portion of the gland.

As a rule the breast is not noticeably enlarged, although more or less prominent bosses may appear on different parts of the organ. In many instances the patient's attention is attracted by the presence of a more or less constant dull, aching pain, which, in approximately one-half of all cases, accompanies beginning abscess formation. This pain is rarely severe, and in many instances is scarcely noticeable.

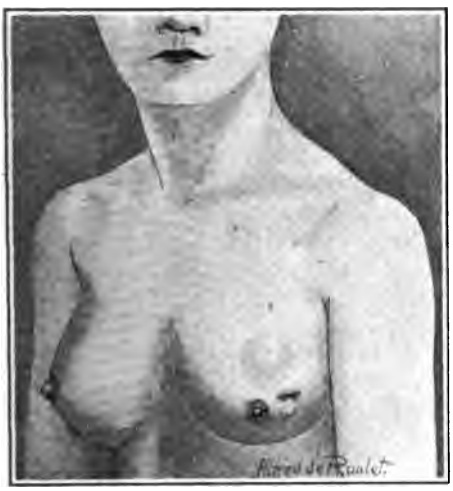

FIG. 1. Tuberculosis of Breast.

On examination a case of primary tuberculosis of the breast will show the presence in the gland of one or more, usually two or three, irregular flattened masses of variable consistence, which are inseparable from the gland tissue. They are not particularly sensitive, and vary from the size of a hazel nut to that of a hen's egg, and while the masses are more or less separated from each other, they usually lie in the same quadrant. Abscess formation occurs rather early, and the tendency to involvement of the skin is marked. Discharging sinuses are present in a large proportion of all cases. In advanced cases the nipples are often retracted, while the axillary glands are enlarged and matted together.

"Cold abscess" is not often encountered. When present it occurs as a circumscribed, elastic fluctuating tumor, with sharply defined outlines. The surrounding tissues are not infiltrated, fistulæ do not form, and the skin is not involved. The condition is likely to be mistaken for a simple retention cyst; the history of the case, however, should afford some assistance in the differentiation.

The following case histories are fairly typical:

Case 1.—Patient, aged twenty-six, rather pale and anemic, but fairly well-nourished. Two years ago she noticed a rather painful lump about the size of a walnut in the right breast. Attributing the condition to a bruise, she paid no particular attention to it. The mass gradually increased in size, and two smaller masses appeared. The skin over the first nodule had recently broken down, and a discharging sinus appeared. Of the two smaller masses, one was firm and not adherent to the skin; the other was somewhat softer, and especially in the central portion, and dimpling followed any attempt to pinch up the overlying skin. The axillary glands were enlarged. The patient recovered promptly after the complete removal of the breast and axillary lymphatics, and six months later has shown no evidence of a recurrence. On section of the breast several small caseous nodes were found in the upper outer quadrant, while caseous masses were found in two or three of the removed lymph glands. (Fig. 1.)

FIG. 2. Tuberculosis of the Breast.

Case 2.—Patient forty years old; mother of eight children. About two years ago she noticed a slight swelling in the right side of her neck, which increased slowly for about three months, since when there has been little or no change. A year ago she began having more or less severe aching pain in the right breast. On examination several hard, flattened nodules, varying from the size of a pigeon egg to that of an English walnut, were detected. These masses were hard and non-fluctuating, with vaguely defined outlines; they were firmly attached to the glandular tissue, and could only be moved with the breast. The axillary and cervical glands were enlarged, but the nipple was not retracted. (Fig. 2.)

As to the prognosis in any given case of tuberculosis of the breast, if the condition develops primarily in the breast, the complete removal of the tuberculous tissue may be expected to give very satisfactory results, but should the condition develop secondarily to a pulmonary tuberculosis very little can be expected. In the primary cases it may be necessary in some instances to remove the entire breast, together with the enlarged lymphatics, while in less extensive cases, excision of the affected lobes is sufficient.

In *syphilis of the breast* the lesion may appear as an initial sclerosis of the nipple and areola, or more commonly as a gumma, or a diffuse infiltration of the gland.

The mammilary chancre occurs as a typical chancrous erosion, or as an indurated ulcer or fissure. It is usually single, but in a few cases multiple lesions are observed. The chancre may be located on the nipple or the areola, and, as a rule, is depressed rather than elevated. (Fig. 3.) Ulceration is frequently present. The borders of the induration are not clearly defined. The lymphatics leading to the axilla are enlarged and indurated. Pain is often present, and when the nipple is involved is likely to be severe.

The gumma occurs as a more or less circumscribed tumor which may develop in any portion of the breast. In its developing stage it is hard; free from pain or tenderness, and moderately projecting. The overlying skin is freely movable, and the nipple is not retracted. Later, the gumma softens, and the skin becomes adherent, discolored and infiltrated, and breaks down, forming an excavated ulcer. (Fig. 4.) This condition is very often confused with carcinoma, but the presence of syphilitic lesions in other parts of the body, as well as the rapid improvement which follows the administration of the iodides is sufficient to establish the diagnosis.

The infiltrating form presents a diffuse, ill-defined, painless induration, which may involve the entire breast or which may be limited to one or more lobes. The skin is unaffected in the early stages, the nipple is not retracted, and the axillary glands may or may not be enlarged. As with gummata, softening and ulceration may be expected.

Simple retention cyst appears as an isolated, rounded, elastic tumor, with clearly defined outlines, which develops rapidly and with little or no pain or tenderness. The size of the cyst is variable, but ordinarily ranges from the size of a filbert to that of a goose egg. The tumor is freely movable, does not infiltrate surrounding tissues, and is not accompanied by changes in the overlying skin, as adhesions, discolorations or dimpling. The nipple is not retracted, and the axillary glands are not affected. It may appear at any time between puberty and the menopause, but is most frequently encountered in young and prolific married women.

The cyst is purely local in character, and is due to the accidental obstruction or occlusion of a milk duct. This occlusion may be due to trauma, scar following operation, to prolonged suppuration, or to more or less transient inflammations involving either the nipple or the gland. In many cases, however, the exciting cause can not be determined.

On section the cyst is found to be thin-walled and filled with a more or less turbid fluid, which varies from a pale yellow to a yellowish brown or red. The clinical picture is very clearly shown in the following case:

Patient, well-nourished young woman, twenty-four years old; unmarried. Two months ago noticed ovoid lump about the size of a small walnut immediately below the left nipple. The discovery was made

by accident, as there had been no pain or tenderness to attract her attention. There was no history of previous injury or disease. On examination the tumor was found to be smooth, elastic and freely movable. No fluctuation. The overlying

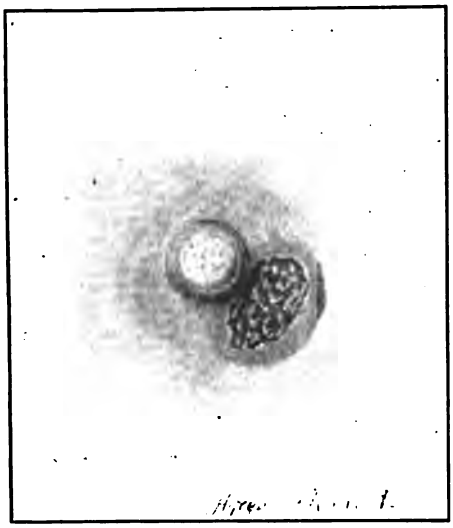

FIG. 3. Chancre of Nipple and Areola.

skin, the nipple and the axillary glands were perfectly normal, as was the opposite breast. A diagnosis of simple retention cyst was made, and, on operation, a thin-walled cyst, containing approximately an ounce and a half of pale, somewhat opalescent fluid, was dissected out.

A rather uncommon variety of retention cyst, the galactocele, or milk cyst, occurs during lactation as the result of the blocking of a milk duct. The cyst at first contains pure milk, but eventually the watery portion may be more or less completely absorbed, leaving behind a soft, putty-like mass. Certain authors assert that calcification of this mass may occur, but this assertion I believe to be entirely unsupported, as I have never been able to find even a single case reported where such calcification has occurred.

During its entire course a galactocele is free from pain and tenderness. The skin is not discolored, and the nipple remains unchanged. The axillary glands are not involved, and the general health is not affected. A soft, painless, fluctuating, more or less globular tumor, appearing suddenly during lactation, with no signs of inflammation, may be safely diagnosed a galactocele. With a cyst of long standing, the swelling increases with each successive pregnancy and decreases somewhat with the cessation of lactation.

Simple retention cysts are of comparatively slight pathological significance, and are not infrequently mistaken for periductal fibromata. In middle-aged women there may be some difficulty in differentiating them from senile parenchymatous hypertrophy.

Eczema of the nipple and areola occurs most frequently in women under forty years of age, especially during pregnancy and lactation. In the beginning the nipple becomes red, swollen and painful. Crusts and fissures soon form, and the affection may spread over the breast as a more or less circular patch. As a result of the swelling of the surrounding tissues, the nipple appears decidedly flattened. Pain and itching are constant symptoms. After the menopause a condition somewhat resembling eczema may develop. This affection, Paget's disease, presents a "florid, intensely red, raw surface; very finely granular, as if the whole thickness

FIG. 4. Ulcerating Gumma of Breast.

of the epidermis had been removed." There is a profuse, clear yellow exudation. The edge of the patch is often somewhat raised, and is sharply defined from the

surrounding tissues. The contour is circinate, and composed of more or less regular arcs of a circle. As the disease advances, irregular patches of epidermis are seen scattered over the excoriated surfaces, the patches appear dry and glazed, and are said to be characteristic of the disease. Even in the early stages there is considerable superficial induration, the indurated area being approximately an eighth of an inch thick, and "feels like a penny through a piece of cloth." In eczema there is no induration, the tissues are soft and the edges of the eczematous patch are not sharply defined. Itching is an early symptom in eczema, and a late symptom in Paget's disease. In eczema there is less rawness and more of a punctiform redness, while the papules, vesicles and pustules, as well as the occasional exacerbations which characterize, are not seen with Paget's disease. In either condition, lymphatic involvement does not occur until late in the disease.

The prognosis is favorable in eczema, or while the condition may not yield readily to treatment, it is entirely curable. Paget's disease, on the contrary, resists all treatment other than operative, and in the course of from one to five years after its first appearance inevitably terminates in cancer.

[Written for the MEDICAL BRIEF.]

Repair of the Pelvic Floor or Colpoperi Neorrhapy and the Structures Involved.

BY BYRON ROBINSON, B. S., M. D.,
Chicago, Ill.

(Continued from page 367.)

The pelvic connective tissue comprises the connective tissue between the pelvic fascia and the pelvic peritoneum. It serves to connect and maintain the relation of the pelvic organs as a bed on which the viscera rest, to safely distribute nerves and vascular channels, as a buffer to avoid traumatism, and as an elastic compressible medium. It frequently consists of fine, shiny planes, and hence allows invading infection to cleave them asunder and progress in various directions. However, the connective tissue of the pelvis may be areolar, fine and delicate, as white as snow, and as soft as eiderdown, reminding one of hoar frost. It may gradually glide from the softest cellular wide-meshed, spongy form, to the firm, fibrous, hard lamina or fascia lining the pelvis, the loose connective tissue pads, the interstices between muscles and organs and about vessels and nerves. It also fills irregular spaces. It is distributed quite irregularly. It allows organs to move, to expand and contract, and to return to their normal spongy base without losing their integrity or adjacent relation. A large mass of connective tissue exists, having a triangular outline, between the bladder and posterior pubic surface, known as retropubic fat. This part varies in position and shape from pressure by attitudes of the state of the body and distention of adjacent viscera. A certain amount of tissue is collected between the cervix, vagina and bladder, in which is distributed a large venous plexus, and through which the ureter traverses. Large collections of connective tissue are located along the lateral surface of the uterus, especially about the cervix. It also extends well laterally between the blades of the broad ligament, especially extensive along the base which is traversed by large plexuses of valveless spiral veins. It is when these veins, set in well-fitting connective tissue sheath, become straight, irregularly dilated and torn from their connective tissue bed that the woman becomes ill. Her pelvis is excessively congested, and excessively filled with residual venous blood.

The connective tissue, chiefly with some muscular fibers, covered by a dorsal and ventral peritoneal blade, constitute the broad ligament. However, each vessel and nerve carries its own connective tissue into the broad ligament. Between the rectum and vagina there is also a collection of areolar tissue, enabling the canals to glide on each other without damage, and some exist between the rectum and sacrum. The pelvic connective tissue located between the pelvic peritoneum and pelvic fascia is all more or less connective. It is like connective tissue elsewhere, and subject to similar disease. Great importance is attached to the distribution of the pelvic cellular tissue

from the clinical fact that the abscesses arising in it progress in certain directions, and experimentation has defined the routes. This tissue is involved in parametritis and perimetritis, and in pelvic phlegmon. An abscess originating at the side of the cervix generally moves along the pelvic floor at the base of the broad ligament. It then progresses along the region of the round ligament into the iliac fossa. The abscess of the pelvic cellular tissue will progress in the direction of the least resistance, cleaving the fine fascial planes. It may rupture over the iliac crest, over Poupart's ligament, into the rectum, bladder, vagina, and through the perineal body, or, rarely, into the peritoneal cavity. The pelvic connective tissue may become infected from the ischio-rectal fossa, and *vice versa*, by the infected lymphatic sheaths which follow all vessels and nerves entering or leaving either pelvic or ischio-rectal space.

A phlegmon in the pelvic tissue generally arises from an abortion or labor, acute infection. The author performed sixty autopsies on females for the special object of studying the relation of pelvic peritonitis to the pelvic subperitoneal connective tissue. Ten per cent of the subjects having pelvic peritonitis had pelvic cellulitis, which, in every case, was subsequent to or a continuation of the superimposed pelvic peritonitis.

Ninety per cent of pelvic peritonitis existed without the least sign of pelvic cellulitis, the subperitoneal connective tissue being as white as snow. The masses felt in the pelvis through the vaginal fornix are nearly always peritoneal exudates perchance, encasing the ovary and oviduct.

The pelvic subperitoneal connective tissue, the subserosum, is padding material protecting beds, a connection of organs and conductor of vessels and nerves. The nomenclature of the local portions of the pelvic connective tissue are parametrium, paracolpium, paracystium and paraproctium. The above names indicate sheaths of connective tissue enveloping the respective organ. The pelvic connective tissue might be localized in three regions, viz.: (*a*) The loose connective tissue lying in the portion of the pelvis anterior to the broad ligament extending especially anteriorly toward the inguinal canal. Poupart's ligament, round ligament, the cave of Retzius, the subserosum of the ventral abdominal wall, dorsal surface of the bladder, and the utero-vesical pouch.

(*b*) Loose connective tissue lying in the portion of the pelvis dorsal to the broad ligament, and extending especially dorsally and laterally as paraproctal and parasigmoidal tissue.

(*c*) Loose connective tissue lying at the external lateral border of the base of the broad ligament extending especially toward the iliac fossæ and the mesocola, and proximalward to the para-renal tissue. The pelvic connective tissue could be localized by the designation para-vesical, para-uterine and para-rectal. It might be designated as the vesical and rectal mesodermic beds of the pelvis. Forced injection of traceable fluids into the pelvic connective tissue demonstrates that the fluids follow the highways of the great masses of tissue which are the directions of least resistance. Pathologic fluids assume the same routes. The signification of the pelvic subserosum becomes evident when it is remembered that as peri-neural, peri-vascular and peri-lymphatic sheaths it accompanies these structures into the parenchyma of organs internal and external to the pelvis. It can thus convey infection to different regions.

The Pelvic Sphincters.—The pelvic sphincters are the anal, the vaginal, the uterine, the urethral, the ureteral and those of the oviduct. They are landmarks, points for anatomic, physiologic and pathologic consideration.

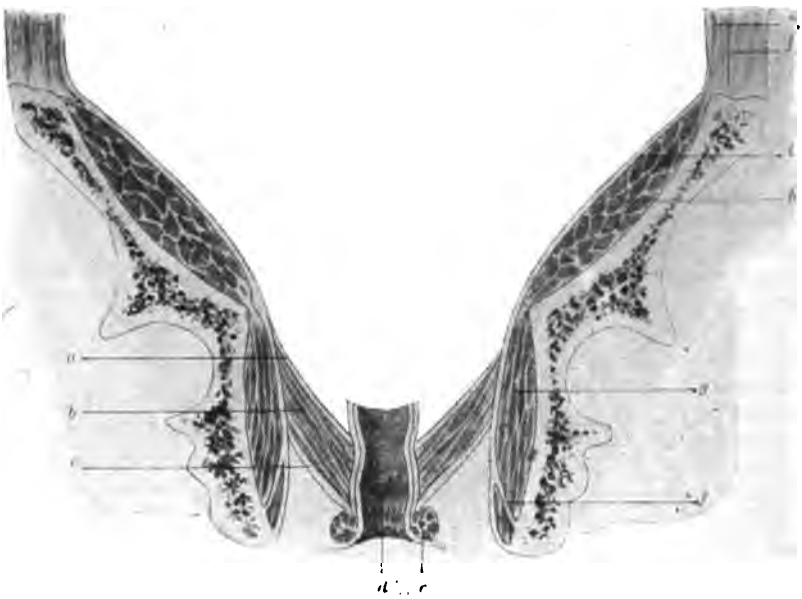
The object of a sphincter is to guard an orifice, to allow periodic retardation and passage of matter by timely contraction and dilatation. It may be located in a tube wholly in relation to the mucosa or partially in relation with mucosa and integument. Sphincters, or ring muscles, are subject to frequent congestions and decongestions, contractions and relaxations. They functionate periodically, and in a state of rest are closed. They possess a complicated nerve, a high blood and large lymph supply. They are liable to malignant growths, cicatricial strictures, and are occasionally the seat of severe pain from wounds of the margin.

FIXATION OF THE TRACTUS GENITALIS.

A. PELVIC DIAPHRAGM (PRIMARY SUPPORT.)

Diaphragm pelvis consist of muculus levator ani plus its proximal and distal fascia. What maintains the genital organs in their normal positions?

(*a*) The form and function of the pelvic floor (levator ani with its proximal and distal fascia). (*b*) The position of the genitals and the adjacent viscera. The mesenteries of the tractus genitalis (ligamenta lata) are not for mechanical support. They are to conduct vessels, nerves, and to maintain structures in order for function. It is true that the ligamenta sacro-uterina acts as vigorous supports if placed on tension, but in their present normal state of existence they simply direct the cervix dorsalward. The vagina extends from the pubis to the cervix, and the sacro-uterine and the ligaments extend from the sacrum (rectum) to the cervix. Hence the vagina and sacro-uterine ligaments act as a supporting beam on which the cervix and uterus is supported. The same story, that the thoracic and abdominal viscera are chiefly maintained in position by their respective walls, is true as regards the position of the pelvic viscera and its walls. The so-called uterine ligaments (mesenteries of the genitals) act only in pathologic relations, as in sacro-pubic hernia. As an anatomic demonstration that the pelvic floor supports the uterus, one can observe (with evacuated bladder and rectum and uterus in physiologic position) that the transverse vaginal slit in the pelvic floor lies two inches ventral to the cervix (*i. e.*, the corpus uteri lies dorso-ventral across the transverse vaginal slit). If pressure be exercised on the corpus uteri exactly as intra-abdominal pressure is applied, the previous position of the uterus will not be endangered, *i. e.*, it will not enter the vaginal slit, but simply force the pelvic floor distalward. In other words, the pelvic floor, the distal wall of the pelvis or levator ani, with its proximal and distal fascia, maintains the tractus genitalis (uterus) in the normal physiologic position. If one wishes (in the cadaver) to force the uterus through the vagina, vaginal slit in the pelvic floor, the hand seizes the fundus and corpus, while the cervix is pushed vigorously distalward in the vaginal slit, where the cer-



THE FASCIAL AND MUSCULAR PELVIC FLOOR.

FIG. 3. A transverse mesial section of the pelvis presenting the pelvic floor fasciæ and muscles; a, levator ani fascia proximal; b, levator ani muscle; c, levator ani fascia distal; d, rectum; e, sphincter ani external; f, Alcock's canal; g, obturator muscle internal; h, iliac muscle; i, iliac fascia; j, muscles of the abdominal wall; k, fascia transversalis.—ROBINSON-SCHOELER.

vix may be observed in the introitus vaginæ.

If the pressure is removed from the uterus it returns to its normal position. One cannot force the corpus and fundus through the vaginal slit with any ordinary hand power. During energetic forcing of the cervix through the vaginal slit the ligamenta lata and ligaments sacro-uterina are scarcely put on tension (they are entirely secondary supports). If all the uterine ligaments are severed and the experiment repeated, the cervix can be forced through the vagina to the introitus only. The impossibility of forcing the corpus and fundus through the vaginal slit and introitus vaginæ is due to the increasing volume of the corpus and fundus on account of the addition of the oviducts, vessels, nerves and ligamenta lata. The sacro-pubic hernia of senescence is due to atrophic conditions of the genitals which glide through the vaginal slit from diminutive volume. Ziegenspeck claims that sacro-pubic hernia (uterine prolapse) is due to the difference between intra-abdominal pressure and atmospheric pressure. Hence the primary support of the pelvic viscera (genitals) is the pelvic floor—levator ani with its proximal and distal fascia. By relaxation it includes the tractus genitalis in splanchnoptosia.

Diaphragm thoracis resembles diaphragma pelvis in physiology and anatomy. Both have (*a*) a similar fixum punctum (circulatory bony origin), (*b*) similar punctum mobile (central tendon), (*c*) both support superimposed viscera, (*d*) both have three apertures for visceral transmission, (*e*) both diaphragms are respiratory, (*f*) both muscles, by constriction, limit the apertures of visceral transmission, (*g*) both contract as a single muscle, (*h*) both share in splanchnoptosia. They differ in that contraction of the pelvic diaphragm draws the three visceral apertures proximalward and ventralward, while contraction of the thoracic diaphragm draws the visceral apertures distalward and dorsalward.

(B.) LIGMENTA UTERINA (SECONDARY SUPPORTS).

All uterine ligaments arise from the pelvic wall and become inserted in the lateral borders of the uterus. They act as guy-ropes, to maintain the uterus in a physiologic position in order to functionate. The ligamenta lata, the real neurovascular, visceral pedicle is a physiologic support only, not a mechanical, serving as a conducting bed for vessels, nerves and tubular viscera. These secondary uterine supports in genital ptosis become primary, which is a pathologic condition.

MOVEMENTS OF THE TRACTUS GENITALIS DURING RESPIRATION.

To demonstrate that the diaphragma pelvis is a muscle sharing in respiration, one need only to witness a single perineorrhaphy. Whence the proximalward and distalward movements of the levator ani are evident. To prove that the genitals share in respiration, one need only to observe the regular motion of six-month gestating uterus, or the motion of the vagina and uterus in a coughing anesthetized patient, whence not only the blue vagina everts through the vaginal slit, but the uterus may also present at the pudendum. The genitals and pelvic floor move with respiration. The respiratory movements of the genitals are the chief factors in genital ptosis. To illustrate: If, in a case of uterine prolapse, or better, sacropubic hernia, the uterus may be returned to the pelvis, and the patient told to force it distalward. She immediately inspires deeply, whence she retains the inspired air, fixes the thoracic diaphragm, and forces the uterus rapidly distalward through the vagina external to the pudendum. She accomplishes this act by respiratory motion. With relaxation of the pelvis the uterine fundus passes dorsalward, and the cervix, by this mechanism, gains entrance to the vaginal slit in the pelvic floor, whence intra-abdominal pressure forces the uterus distalward. If the uterus loses its volume, becomes atrophic, respiratory movements may force it distalward through the vaginal slit without loss of integrity of the pelvic floor.

The continual respiratory trauma when visceral supports are deranged, produce progressive sacro-pubic hernia. From study of the anatomic supports of the genitals it is evident how irrational are the surgical attempts to fix the uterus in some preconceived position by means of hysteropexy, or the shortening of some secondary uterine support. It appears that the function of respiration is not con-

fined to a single location in the spinal cord, but extends to wide areas on its egress nerves, so that man's trunk is a respiratory apparatus closed at the proximal and distal end by a diaphragm—both actively involved in respiratory movement. The relaxation of the pelvic floor and consequent genital ptosis is simply a demonstration of the pathologic anatomy and physiology of respiration. The genitals present various grades of splanchnoptosia. In the first place, the portio vaginalis is found moved distalward in the pelvic axis, the corpus may be in normal anteflexion, but more frequent in a beginning of retroflexion—the whole uterus is excessively mobile. In the second place the entire uterus lies parallel and against the sacrum (rectum). The cervix is not infrequently fixed through parametritis dorsal. According to the degree of genital splanchnoptosia arise pain in the back and sacrum, radiating pain in the extremities, menstrual disturbances, venous congestion and constipation. Later the cervix projects through the pudendum. Advanced splanchnoptosia of the genitals presents prominent features of relaxation of the pelvic floor and venous congestion.

ETIOLOGY OF GENITAL PTOSIA.

The chief etiology of genital ptosia is:

(I.) Results of parturition, *i. e.*, elongation, separation or laceration of the pelvic floor tissue (the levator ani muscle and its proximal and distal fascia).

(II.) Atrophy of the genitals.

(III.) Respiratory movements forcing the genitals distalward (constantly forcing the deranged genitals in the direction of least resistance).

(IV.) Relaxation of the thoracic and abdominal walls.

(V.) Superimposed splanchnoptotic viscera.

(VI.) Genital sub-involution (infection).

THE TREATMENT OF GENITAL SPLANCHNOPTOSIA.

The treatment should be medical, mechanical, surgical.

(I.) MEDICAL.

One of the essential remedies is visceral drainage. Hot vaginal douche (with salt and alum as ingredients), increased to twelve quarts, which contracts tissue (elastic, muscle, connective), massage, electricity, ample and horizontal rest are valuable means. The boroglyceride tampon serves as an excellent remedy. It is hygroscopic, and may be prepared so that it can be worn one to several days.

(II.) MECHANICAL.

The horizontal position should be used as much and frequently as possible. Abdominal binders (in which may be placed a pneumatic rubber pad), Achilles Rose's adhesive strapping. Galant's corsets furnish much comfort. Various kinds of pessaries may be worn.

(III.) SURGICAL.

Since the uterus is supported by the pelvic floor rational surgical procedures should be applied to it in splanchnoptosia. Relaxed pelvic floor means relaxed, elongated fibrous separation of the levator ani with its proximal and distal fascia. Hence perineorrhaphy should include the careful repair of the levator ani with its proximal and distal fascia. It is fascia that supports, not muscle. Ventral colporraphy aids in forcing the bladder proximalward and narrowing the vaginal exit. The most effective and enduring operation for splanchnoptotic genitals is: (*a*) amputation of the cervix (if required). (*b*) ventral colporrhaphy, (*c*) and extensive colpo-perieorrhaphy, *i. e.*, an extended Tait flap-splitting operation with reunion of the torn muscle and fascia of the levator ani. In cases of uterine atrophy extensive vaginal narrowing is required. For splanchnoptosia of the genitals hysterectomy should not be performed (as it renders supports less efficient). The uterus is the key to the support of the genital viscera. I have seen subjects of splanchnoptotic genitals where the uterus had been removed and subsequently the everted, distended vagina extended to the middle of the thigh with almost hopeless views of repair. As to suspending or fixing the genitals to the abdominal wall proximal to the pelvis it is an irrational operation, unphysiologic and harmful. The anatomy and physiology of the genitals belong to the pelvis.

Ventral abdominal hysteropexy should not be performed in a reproductive subject. Also patients do not present symp-

toms indicative of malposition of the uterus. The position of the uterus has no special relation to disease. As the symptoms do not emanate from the position of the uterus, fixing it will have no relation to the symptoms (except to exacerbate them). The symptoms of patients with retroversions, for example, emanate from other causes than the uterus.

[Written for the MEDICAL BRIEF.]

Plaster of Paris Dressing for Fractures and Articular Inflammations and the Abdominal Plaster Belt for Atonia Gastrica.

BY DR. A. ROSE,
New York City.

Plaster of Paris dressing for fractures was invented and introduced by the Dutch military surgeon, A. Mathijson, in the year 1852. His mode of dressing which was followed for a time, was the following: First, the bony prominences were covered with wadding, next a flannel bandage wound around the extremity, and finally the plaster bandage applied. The literature on this new method became very voluminous, as one writer says it assumed monstrous dimensions. As a matter of course it consisted to a great part of polemic; like everything new, the new way of dressing was bitterly condemned by many writers, probably by such who had tried the plaster of Paris dressing without knowing how to do it properly. From his experience in the Franco-German war of 1870 Burow relates how the plaster of Paris dressing had been applied in many instances in such faulty way that gangrene and infection of wounds (compound fractures), were caused by gross errors in the technic.

But Burow calls attention to a method of applying the plaster, namely: the application of flannel bandages before the plaster of Paris bandages were applied, a method which he does not approve, which, as far as I know, had been abandoned, but is revived again.

Speaking of his observations during the campaign, he tells that most surgeons, even those of highest ranks, applied the plaster of Paris dressing in a wrong way; namely: over flannel or muslin bandages with which the extremities had been bandaged before the plaster dressing was applied. Every dressing of an extremity with ordinary bandages, however skilfully applied, and no matter how elastic the material, exerts an unequally distributed pressure upon the soft parts. This is a fact which can be demonstrated by the more or less marked impressions the single tours of the bandages leave on the skin; impressions which disappear after longer or shorter time, after the effect on the circulation caused by unequally distributed pressure has regulated itself again. Such pressure, however, and its effect on the circulation are a disadvantage which does not exist when the plaster of Paris has been applied *lege artis* on the bare skin. When the bandage is removed, we see on its inner surface an exact cast of the surface of the extremity which had been encased; the plaster shows, not only every little hair, but also, when we apply a magnifying glass, the finest details of the skin pores, eruptions, etc. But supposing the flannel bandage should not have caused any disturbance of circulation, and should have been of no disadvantage at all, we still find how much preferable the application of the plaster of Paris dressing applied directly to the skin will offer:

1. It is cheaper.
2. The flannel or any other underlying material makes the dressing heavier.
3. The dressing without flannel or other underlying material takes less time, which is especially of importance in military surgery.

Some anonymus in criticising a book of mine, in which the effect of plaster of Paris dressing on circulation and innervation was spoken of, says: "What effect upon circulation or innervation does plaster of Paris exert in fractures or arthritis, other than that of equable immobile surface pressure called fixation?" This was written about two years ago in a scientific medical journal.

The principle of uniform pressure I had in view when I suggested the abdominal plaster belt in case of atonia gastrica, that is abdominal relaxation, to

support in first instance the relaxed abdominal muscles, in second instance to bring the displaced abdominal organs again into their physiological position, and finally to relieve gastric and nervous disorders caused by such relaxation and displacement.

In the preface of the book referred to (*) I said: "This belt is something more than such a support, as is given by an ordinary abdominal supporter or bandage, for it exerts an effect on circulation and innervation which can only be compared to that of plaster of Paris dressing in case of fracture or arthritis."

The practical use of the abdominal plaster bandage which was described first in THE MEDICAL BRIEF some years ago, should be perfectly clear to every physician. It is certain that it does away with pernicious effects frequently caused by the ordinary abdominal supporters. The uniform pressure has enormous advantages over the changing one of those supporters, quite apart from the injury done to the spinal musculature and lumbar nerves by the ordinary bandages. I have noticed that the benefit derived from the plaster belt is, in many instances, a permanent one, because we may, by this means reduce the volume of the abdomen permanently, and the diminution of abdominal volume is rapidly followed by reduced engorgement. How well the abdominal plaster belt acts in case of pain can be demonstrated in gallstone colic; here it can give relief almost as promptly as a morphine injection. But these and many more indications for the plaster belt I have shown in numerous writings to which I beg to refer. These remarks are intended principally to show the similarity of the effect of the abdominal plaster belt to that of plaster of Paris dressing.

PRACTICAL NOTES.

NO. III.

Nervous Eructation.—We all have had, in the course of our practice, patients with spasmodic paroxysmal ructus by which nothing but atmospheric air is expelled, and in which cases there is not necessarily any other stomach disorder present. This symptom is merely one of the many manifestations of neurasthenia or hysteria. These ructus do not happen during the night. In some cases they last a few minutes; in others several hours. They may happen without any special cause, or in consequence of some excitement; in some instances during or soon after meals, some cases have been described in which the ructus happened while the patient was standing or sitting, but never when in the recumbent position; the attacks would cease as soon as the patient occupied the horizontal position.

These are practical notes, and I will be as brief as possible, not enter into literature and detailed explanation, but confine myself to the fact that such patients swallow air and expel it again from the stomach into which this air had entered.

There are cases of this kind which serve for demonstration in the clinics; they are treated with all kinds of medicines, bromides, asafetida, valerian, strychnin; in fact, all kinds of anti-hysterical remedies, but they prove obstinate towards drugs, and one case may serve a lecturer for years to bring it before the class. A very good, and in, perhaps, most cases, effective remedy, is to order patients to keep the mouth wide open, in order to prevent the act of swallowing, to have them place a wedge between the upper and lower rows of teeth, the like as the dentists use when they administer laughing gas or fill the teeth. Have the patient retain the wedge as long as possible, and place it between the teeth again as soon as the eructation begins. In some cases we have, in order to prevent the symptom with certainty, to keep the upper and lower jaws apart *ad maximum*, in others, especially in later stages of the course of treatment, less and less small wedges can be selected.

There are cases, it is true, in which complications exist, and in which the wedge alone will not suffice, but in the majority this very simple means will give perfect satisfaction, and make all medical treatment superfluous.

Strychnine Injections in Cases of Hysteria or Neurasthenia.—Each and every one of us every-day practitioners has had his patience tried when treating cases of hysteria. We exhaust all our skill, more or less, in vain in some instances. We pre-

* Atonia Gastrica, by A. Rose and R. C. Kemp. Funk and Wagnalls Company, New York, 1905.

scribe with unsatisfactory results, sometimes asafetida, valerian, gold, bromides; in fact, we may go through the whole litany of drugs recommended, and our patients are obstinate to respond. None of all the means at our disposal will compare in efficiency with strychnine injections, one injection of 1/30-grain for twelve consecutive days. Not only will this treatment cure the symptoms promptly, but permanently at least for years in the great majority of cases. And what a triumph if such a patient has been treated in vain before for a long period, and by many physicians. The same patient may have taken strychnine by the mouth for months, or even for a year, and longer, without the slightest, or with very little benefit. Here the action of strychnine taken by the mouth, is moonshine when compared with its effect hypodermically. There are cases, however, in which those injections of 1/30-grain of strychnine should form only part of the therapy, cases, namely: in which there is abdominal relaxation; that is, relaxation of the abdominal muscles manifested by the presence of splashing sound. Such abdominal relaxation, called atonia gastrica, or gastroptosia, may be the cause of all the nervous symptoms, and has to be relieved by means of plaster strapping, suggested by me, and described in THE MEDICAL BRIEF, and more fully in my book: "Atonia Gastrica." Therefore, let us examine in all cases of hysteria or neurasthenia first for the splashing sound, and relieve before we commence with the injections the relaxation of the abdominal wall. The result will be marvelous. A very important point in this treatment is that not only the hypodermatic syringe is thoroughly sterilized, by having it in boiling water for some time before we make an injection, but to be positive that the strychnine solution is aseptic. There are so-called ampullæ in the market, each one containing 1/30-grain of strychnine nitricum solution. Since I have used these ampullæ, instead of the ordinary hypodermic tablets, I have never seen an inflammation follow the puncture, much less an abscess. Of course, the skin at the point where we intend to inject has to be sterilized according to antiseptic rules.

There is another advantage characteristic of this treatment. The patient has to come to our office or we have to go to the house for twelve consecutive days, and this impresses the patient favorably; seeing something done every day by the physician himself instead of taking a medicine in which confidence may have been lost to some extent, and in which we can ourselves not have much confidence.

Inadequate Nutrition and Drug Addiction.

BY SAMUEL S. WALLIAN, A. M., M. D.,
New York.

In a pamphlet reprinted from the *Medico-Legal Journal*, entitled: "A Review of Drug Consumption and Alcohol as Found in Proprietary Medicines," Professor Grinnell, late Dean of the Medical Department of Vermont State University, made this astonishing statement:

"For a great many years I have believed that every human being craves some artificial stimulant. Ask yourself what your stimulant is. What is mine? What is my neighbor's? We all have one, and after thirty years in practice I can truthfully voice the opinion generally entertained by the medical profession that every human being craves and requires some artificial stimulant."

If intended as an argument corroborating the theologic theory or Mosaic tradition of the Fall of Man, the statement has some plausibility. Logically, biologically and physiologically it is entirely unwarranted, and emanating from such accredited authority, it is inexplicable.

To admit the truth of this preposterous assumption would be to impugn the author of the race as an egregious bungler.

In discussing the Education Bill before the English Parliament Dr. Forbes Winslow startled his hearers by asserting that, "According to statistics on insanity it can be shown that before long there will be actually in the world more lunatics than sane persons. The burning problem of the day is how to prevent this increase of insanity? What is the use of wasting

time and energy on an education bill when we have before us the absorbing problem, the contemplation of an insane world to deal with?"

Following Professor Grinnell's line of reasoning, shall we say that there was a vein of insanity in the original Adam which is being legitimately transmitted even to the present generation?

Preliminary to a search for some fundamental cause or causes on which the foregoing assumptions must have been based, the following syllogisms seem apropos:

A normal child, born into a normal environment, and fed upon normal food, barring accidents, will develop into a normal man.

A normally born, bred, fed, environed and exercised man will crave neither stimulants nor narcotics, nor will he drift into insanity.

The craving for stimulants and narcotics is always artificial and acquired.

Insanity, when not of traumatic origin, results from disordered or excessive mental activity, and is, therefore, also acquired, and not in any ordinary sense hereditary.

Both mental bias and acquired appetites are prima facie evidence of degeneracy, and degeneracy is abnormal.

The question of heredity is confusing, since the word normal is so vaguely and variously defined.

To be normal a child must be born of healthy parents; whereas a large majority of parents are not physically sound.

Again, the modern child is not normally fed. Hence his tendency to degenerate is manifest at such an early period that the superficial observer is apt to attribute any marked physical or physiological peculiarities to heredity.

For example, in an increasingly large number of cases, Nature's source of infant nourishment, the mother's breast, is denied the child, and this normal aliment, mother's milk, warm from its living fount and uncontaminated by contact with the air, or with any form of artificial container, or dietetically modified by one or another artificial process of preservation, is substituted by artificial pabulum, or by milk drawn from the udder of an animal which secreted it for the young of its own kind, instead of for a human being. Even this cow's milk is never fed to infants in a fresh condition, but always, necessarily, after it has been kept some hours, and has been subjected to some one of the various preserving processes, either heat, cold or the addition of more or less objectionable chemical preservatives.

No artificial food can be made to more than approximately simulate mother's milk, and as a consequence the artificially-fed human infant receives too much of one proximate principle and not enough of another; too much casein, and not enough fat and milk sugar. Assuming that any lack of chemical or nutritive elements can be artificially remedied, the fabricated or modified product is invariably, by either heat, cold or other process or manipulation, practically robbed of its original vitality, without which essential quality it can not be made a normal, physiological or ideal nourishment for a child.

The breeding and feeding of domesticated animals has been made a matter of scientific system and absolute certainty. Even in the vegetable world Blodgett and Burbank have demonstrated the entire feasibility of perfecting old and evolving new varieties, if not species, at will. If a tenth part as much had been accomplished in the neglected field of stirpiculture there would be no occasion for the wide divergence of dietetic opinion that now prevails.

It is evident that as regards the improvement of the human race, and the feeding of human beings with a view to perfecting the species, our physiologic chemists and chemical physiologists, as well as the alleged dietetic experts have made little progress. Have they not all along, in spite of their much profound and technical laboratory work, exaggerated superficial data, and failed to get at the fundamental, and yet, no doubt, simple principles of nutritional processes?

Our most expert analytical chemists have not yet succeeded in preparing wholesome or satisfactory nutrition, by synthetic processes, from inorganic material. It is universally admitted that while cell-life is fundamental and indispensable to all life, only plant cells possess the innate power of transforming inorganic into organic substance. It fol-

lows that, since the animal cell requires strictly organic material for its growth, sustenance and repair, the vegetable cell is necessarily its ultimate, and virtually it sole source of supply. The advocates of an exclusively vegetable diet for the human race, therefore, have both scientific deduction and biologic law behind them. Practically they have not made good their claims, because of a palpable ignorance or disregard of the laws of selection and proportion. Among other things they have failed to realize that plant cells, in order to be ideal as sources of cell reproduction, growth and repair, must be supplied in as nearly a normal condition as possible. Any change that destroys their normal structure, disintegrates their molecular arrangement, or decomposes their chemical constituents necessarily interferes with their value as food.

In the feeding of human beings modern fashion, invention and innovation have interposed countless processes of artificial modification and gustatory compromise. In how far have these intrusions revolutionized the primitive feeding habits of the race?

The primal man, who, it is claimed, originated in the tropics, was undoubtedly a stranger to fire. It behooves us to inquire whether the advent of the cook was a dietetic and hygienic calamity.

The cook is the presiding genius of the domestic crematory. He subjects most of his foodstuffs to intense and prolonged heat. Heat effectually destroys cell structure, and when prolonged and intense, to a greater or less extent breaks up chemical combinations, thus reversing the primary process of growth in the plant's history, and relegating its contained mineral elements back to their inorganic condition. By these subtle and as yet scientifically unconsidered changes in structure, molecular condition, and chemical combination may not an apparently perfectly constituted dietary, chemically speaking, be rendered incompetent? May it not be generous in both quality and quantity; ideal as to its proportions of proteids, carbohydrates and fats, and capable of responding to the most exacting chemical analysis as to its mineral constituents, and yet lack that essential organic property of direct and easy assimilability, without which no food can pass final and vital inspection as perfect nourishment?

These minute mineral elements are in constant demand for the building, sustaining and replenishing of gray matter, of brain and nerve tissue, which constitute the dynamo, magnets and connecting wires of the thinking, talking and walking human ego. Then is it not the blind hunger of the robbed system for these refined, concentrated and absolutely indispensable elements that goads the unsatisfied organism and creates a morbid appetite, which seeks a substitute for natural gratification in artificial stimuli, or assuages its clamor by means of nervines and narcotics?

If these postulates are accepted then the argument that all men crave some form of artificial stimulant simply asserts that all men are inadequately nourished.

Again, the substances appealed to are by no means limited to alcoholics and narcotics. It is a long list, and includes sedatives, vital excitants, and mere irritants of nerve-endings, particularly those of taste and smell; ranging all the way from items usually considered harmless, such as tea, coffee and cocoa, to cocaine, cannabis indica, chloroform, cayenne pepper, and even common salt. It includes morphine and other forms of opium, quinine, strychnine, malted liquors, wines, whisky, and all the countless varieties of alcoholics, as well as a nameless array of "tonics" and alleged medicinal makeshifts.

The commonest, most popular and most seductive of all the stimulant-narcotics in use the world over is nicotine. Every other man on the street, in the office and in the home is an habitual and inveterate smoker. Even my lady's boudoir is not safe from invasion. In all the "artistic" illustrations of the current "high-class" literature of the day the hero is almost invariably pictured with a cigar between his distorted lips, or prominently poised in his fingers, as a foreground. To such an extent does this habit prevail that the annual cost of tobacco used in the United States would wipe out the national debt; it would provide an ample fund for endowing all the colleges and universities, and defraying the cost of public instruc-

tion throughout the nation. It would lift the burden of taxation from every town, county, city and State in the Union.

And yet it is a habit which has no ghost of physiologic prop, no shadow of social warrant, and no possible moral or esthetic palliation for its existence. It slowly but surely undermines physical and mental stamina and moral sense. It lulls ambition, invites to ease, and gradually beclouds the finer sentiments in a benumbing atmosphere of apathy and indifference.

Since the use of this seductive narcotic has become so almost universal as to be looked upon as one of the accomplishments of polite society, if not an actual necessity of every day life, no apology is necessary for according it a little further consideration.

The modern bottle-fed infant clamors for some element that is lacking in its daily food. His indolent, ignorant or over-indulgent nurse or mother stills his instinctive plaint by placing between his eager lips a delusive make-shift in the form of a dirty rubber nipple. The swindled little draftsman is made to spend hours every day, practising his "pull," the only returns being some spasms of wind colic, and a little permanent deformity of his malar muscles and the normal outline of his lower facial contour. When the nipple is taken from him he often substitutes his thumb. When he is old enough to desist, from a sense of shame, he bites his nails, or beats the "devil's tattoo," with his fingers, and a little later on takes to pipe or cigar with such a sense of relief and satisfaction that one would think he had been born to the habit. It is Karl Groos who insists that smoking is a survival of the thumb-sucking instinct of infancy. Add to this a blind craving for special elements lacking in his food, he experiences a double incentive to seek something that will both thrill and obtund his over-tense nerves, lull his complaining instincts into temporary satisfaction; something that will waft him to realms of forgetfulness, and paint for him shadowy castles en Espagne.

Summarizing the physiologic effects of the several alkaloids imbibed by smokers, as set forth by those who have minutely studied the subject, the constant symptoms are contractions of the pupils, salivation, cerebral anemia, vasomotor constriction, cardiac asystole, paralysis and convulsions. Tobacco acts upon the spinal and sympathetic systems, and in a lesser degree on the vasomotor system, the cerebrum, cerebellum and nerves of special sense.

It is only a matter of time when the confirmed smoker will acquire a "tobacco heart," "smoker's dyspepsia," chronic insomnia, or some other form of neurotic disease. In extremely sensitive natures the physical and psychic degeneration advances stealthily and steadily until the victim adds another to Forbes Winslow's list of the actually insane.

Finally, it is the inadequately fed who annually swell the great army of psychic derelicts who suffer and sin against their own natures, simply because they lack assimilable phosphorus and other psychic props, in their daily ration.

To admit that Professor Grinnell quotes the prevailing opinion of the profession proves nothing. Pontius Pilate voiced the opinion of the majority when he surrendered Jesus to the mob. And the leaders of the mob proceeded to exemplify the first recorded instance of lynch law by crucifying a man who had committed no legal wrong, but had merely promulgated a psychic innovation that threatened to undermine the treasured traditions and prevailing prejudices of the zealous majority, whose zeal was born of unadulterated ignorance.

Perfection Man's Goal.

BY R. C. CAVE,
St. Louis, Mo.

According to orthodox theology, man was created perfect, fell from his perfect state, and can never be perfect again. The best he can hope for now is to be saved by grace from the consequences of his imperfection. Even the comparatively few individuals of the race who will finally be numbered among the righteous, and received into peace and blessedness at the right hand of the Father, will not

be righteous in reality, but will merely have the righteousness of another imputed to them. If one were to declare it to be his intention to save himself by becoming perfect, instead of by relying on the merits of Jesus, he would be regarded, by orthodox people, as an irreverent blasphemer.

As stated in the last number of the BRIEF, I do not accept this orthodox teaching. To my mind, it is more consistent with the evidence in the case, more reasonable, and more creditable to the Creator, to reverse the orthodox order, and believe that man was imperfect in the beginning; that he has risen, instead of fallen, from his original state, and that he is destined to attain perfection in the end.

Bringing a perfect being into existence only to fall into a hopeless state of imperfection, can hardly be considered an act worthy of an infinitely wise and loving God. It is only by rising into perfection that man can justify his creation, and show forth the wisdom and goodness of his Creator. He can no more "glorify" God by accepting divine favors, earned by a Savior's toil and sweat, and tears and blood, than children can honor their father by living on his bounty and remaining unworthy of it. Only to the extent that it is perfect, can any work manifest the perfection of the workman.

In support of the belief that man will attain perfection hereafter, we have the history of his progress hitherto. His past is a prophecy of his future. The Divine Energy which, by the natural process of evolution, brought him forth from the womb of nature, as a self-conscious and self-active being, endowed with reason and conscience to guide him, and which, through the ages since his birth, has steadily increased his knowledge, extended his power, quickened his moral sense, raised him from savagism to civilization, and made him more and more human, is not, and can not be, exhausted. That Divine Energy is more potent in his life today than ever before; and we may well believe that it will continue to work in him to will, and to do the divine pleasure, until he shall be perfect, even as God is perfect.

But it may be said, evolution is not synonymous with progress. In its processes we find degeneration as well as growth, death as well as life. In regard to the lower orders of existence, this is unquestionably true; but I am not convinced of its truth in the case of man. He is a spiritual being. In him the Divine Energy has evolved itself into a self-conscious, self-active, and self-guiding personality, capable of progress to which we can fix no limit. He is an individuation of the universal principle of life. In him the Divine Spirit has come to birth as a living soul—a self-directing life. He is an incarnation of God; and, while his body may "return unto dust," the God incarnated in that body can not die.

As a spiritual being, man must be immortal; and he is impelled to progress by his environment, and the necessities of his nature. He finds himself in a physical environment in which he is compelled to exert his powers to supply his wants and save himself from suffering; and, through such exertion, his faculties are developed, his knowledge is increased, and he is raised to a higher plane of being. In his moral environment, also, there exists the necessity for struggle. He finds a "law in his members warring against the law of his spirit," and tempting him to wrong. But the final issue of even this is progress. If he resists and overcomes the temptation, his spiritual powers are thereby made stronger, and he is spiritually elevated. If he yields to temptation, he loses innocence, it is true, but he is still on the road to virtue, which is better than innocence. Even through doing wrong, he is being brought into the state in which he will be incapable of wrong. Wrongdoing has its penalties, and, sooner or later, must bring the wrongdoer to that condition in which, like the prodigal son of the parable, he will say: "I will arise and go to my father," and from which he will return incapable of being tempted to do the wrong again. Thus, as some one has said, "even when man goes wrong, he is going "righter." His falls are falls upward. His surroundings and necessities irresistibly impel him towards perfection, as his final goal.

[Written for the MEDICAL BRIEF.]

Homeopathy vs. Allopathy.

BY N. SISCA, M. D.,
Killarney, Queensland. Australia.

(Continued from page 377.)

XII.

CONCLUSION.

Such, then, is homeopathy. Neither a theory, nor an hypothesis, likely to be exploded or set aside from one day to another, but a workable, and, to all appearances, successful, system of therapeutics; founded on a great principle, which, though not quite universal in its applications to the treatment of disease, yet covers such a vast area of the field of medicine as to make its limitations, whatever they may be, hardly worth mentioning. A principle which enables the physician to discover a meaning, and find a clew to the selection of his remedies in every symptom of disease, no matter how trivial and unimportant it may seem to be; a principle which, as the homeopaths maintain, robs medical practice of doubt, and of fear, and gives the practitioner the assurance that, if a case is at all curable, homeopathy has a remedy for it; a principle, which, resting, as it does, on the firm basis of a natural law, has made it possible for homeopathy, and the handful of its practitioners, not only not to be crushed out of existence, but to hold their own and keep on progressing through a long, wearisome century of unremitting opposition. That principle is *similia similibus curentur.*

As a system of therapeutics, we have seen that homeopathy possesses a *materia medica*, which is unquestionably richer than our own, and which contains remedies not only for the ordinary symptoms of disease, but also for its so-called modalities. Where is the allopath, for instance, who would think of questioning his patient as to whether a rheumatic or neuralgic pain is on the right or the left side of the body; whether it is better at rest or on moving about, and *vice versa;* whether it is better or worse by pressure; whether an ailment is better in wet or dry, cold or hot weather; whether a patient feels hot, and yet likes hot drinks, is thirsty, and yet takes drinks only by sips; whether a cough is relieved by a sip of cold water; whether an aching tooth feels as if it were too long, etc., etc.? Why, that is worse than nonsense, an allopath would say, and so it would undoubtedly seem to most of us, but what does it matter what we think or refuse to think about it? The fact is there all the same, that it is this kind of nonsense that has done a great deal for homeopathy, and that it is responsible for many of its successes.

The question may now well be asked: What has prevented us from knowing homeopathy, thus depriving us of the opportunity of increasing our knowledge, and widening the range of our usefulness and proficiency as physicians? If there is truth in the homeopathic system of treating disease, Is it right? Is it moral? Is it christian that the small number of those who are known as avowed homeopaths, should be, as it were, the only depositaries of it, and that the millions of people who are under the care of allopathic practitioners, should be denied the benefit of it?

An editorial paragraph in a recent issue of THE MEDICAL BRIEF tells us that no good physician should admit that he has a superior. Quite right, but what makes the good physician? Is it not the experience of a good few among us, who practice in places where there are also homeopathic practitioners, that at one time or another we have had to acknowledge that there are cases in which allopathic treatment fails, and homeopathic treatment succeeds? And is the man a good physician who, having once had such an experience, allows himself rest until he has found out the why and the wherefore of it?

Take a case of pleuritic exudation. What else has the allopathic practitioner to rely upon, in order to promote absorption, but the external application of iodine, with all its accompaniments of burning and a puckered skin, and very poor results withal? The homeopath, instead, more often than not, succeeds in clearing away the fluid from the pleural sac with his bryonia, thus saving his patient not only the untold miseries of the iodine painting, but, what is more, the risk of empyema and death. Does the homeopath always succeed? I do not know; but if he

has succeeded only once, and that as far back as one hundred years ago, and I happen to know it, do you not think I should try it?

I have before me at this moment a recent publication, where, in the course of an article on the alkaloidal treatment of pneumonia bryonin is recommended for the pleuritic pain. Whence does this notion come to us, that bryonin is good for the pleuritic pain of pneumonia? Why has it not been, why should it not be, made known to every allopathic physician, from one hemisphere to the other, that bryonia is one of the most valuable remedies in the homeopathic *materia medica*, which, under the guidance of, and in accordance with, the principle *similia similibus*, Hahnemann first, and his successors afterwards, found out to be almost a specific for pleuritic pains, as well as for the reabsorption of pleuritic or other serous exudations? At a time when everybody else has the avenues of knowledge wide open before him, so that every man, woman and child may know as much as it is possible for them to know, the qualified allopathic physician, who has spent the best years of his life in educating himself, simply throws overboard his intellectual independence, and unconcernedly allows a book, a periodical, or a teacher to monopolize knowledge for him, and to debar him from knowing homeopathy, on the plea that homeopathy is the accursed thing which no self-respecting physician should dare touch.

Quousque tandem, How long shall that be so? How much longer shall we go on playing at "hide and seek" with homeopathy, belittling it in public, and using its remedies in secret? Humanity, as well as our dignity and our interest, all demand that it shall be so no longer.

And, now a word on the much-debated question of consultation with homeopaths, with reference to which I could not do better than quote the following letter, published under the heading, "A Plea for Tolerance," in the *British Medical Journal* of December 26, 1897: * * * "In my opinion (shared, I trust, by a large number of your readers), our past conduct in this matter has been anything but creditable to our good sense, to say nothing of our humanity. I am utterly incredulous of the ill-results for our patients, and the ignominy for ourselves from the practice of meeting homeopaths in consultation. What can be more ignominious than our present position before the public, of declining to meet men who, equally with ourselves, have passed through the legal curriculum, and so earned a right to an opinion? Why not credit these gentlemen with the possession of some tact, some desire to find a point of agreement with ourselves? It is generally admitted that Hahnemann's influence upon our own methods of practice has been and is considerable, and I could easily name a number of drugs which we have appropriated (not always with any acknowledgment) from the homeopathic armamentarium. * * * Our present boycotting attitude towards homeopaths amounts really to social persecution, but 'the blood of the martyrs is the seed of a church.' We have learned something from homeopaths in the past. Why not learn more, if more is to be learned, and so prove to the world that our sole care is that the truth alone shall prevail?"

To which, by way of comment, the following editorial remarks were appended in the London *Monthly Homeopathic Review*, of February, 1898: "The history of all great truths has repeatedly shown them to have struggled through a period of determined opposition to their reception. But the time comes when the struggling gradually ceases, when knowledge increases, when prejudices abate, when the claims of experience make themselves felt, when inquiry and investigation, freed from the shackles of vested and personal interest, become generally and carefully pursued, and the truth shines forth with a light so brilliant that its acceptance can no longer be resisted."

And with no truer words than those could I wish to conclude these notes.

My task is over for the present, and I trust that I have succeeded in giving good reasons for what I said at the beginning, namely, that the controversy between homeopathy and allopathy is of great importance to us, and that homeopathy is worth studying, because there is much in it that is worth knowing. I have spoken plainly, because I wanted to speak faithfully, yet, in spite of that, or, perhaps, be-

cause of that, I believe that these notes will not have been written in vain. And if so, the credit will not so much belong to me as it will to the editor of this journal, whose liberal and far-sighted broad-mindedness, and whose highly commendable practice of placing before his readers both sides of a question, have made it possible for them to be brought before the notice of a large section of the profession. Such a freedom from bigotry, such a spirit of "no fear and no favor," in a medical journal must necessarily go far towards making it a true friend to its readers, and whilst once again expressing my gratitude to its editor, I also express the hope that for a long time to come THE MEDICAL BRIEF will continue to be found in the vanguard of liberal and enlightened medical journalism.

Last, but by no means least, I am only too glad to acknowledge my indebtedness to the London *Monthly Homeopathic Review*, from several of whose yearly volumes I have drawn freely in the compilation of my notes.

A Specific in the Cure of Snake-Bite.

BY C. R. KING, M. D.,

Atlanta, Ga.

Over thirty years ago I was stopping one night with a farmer in Louisiana, and he very kindly offered to tell me of a sure cure for rattlesnake bite. Very well, I was always anxious to learn of a sure cure for anything. So he proceeded to tell me of a visit the summer before to Georgia, during which time he called on his uncle, Judge Franks. And while he and his uncle and a cousin from far out in the Rocky Mountains region were sitting on the piazza a rattlesnake crawled out from under the house. His uncle wanted to kill the snake, but his cousin said not to. "Let me show you something." So he pulled off his boot and sock, and kicked the snake in the mouth with his bare foot until the snake became mad and bit him on the top of his foot. He then went behind the house, took something in his mouth, chewed and swallowed it. He then pulled off the other boot and sock, and by this time the snake was in a coil, very mad, and ready to strike. He needed only to kick the snake when it bit him on top of the other foot. He again slipped behind the house, took something in his mouth, came out, put on his socks and boots, killed the snake, and came into the house. His uncle said, "John, I will give you one thousand dollars if you will tell me what you took when you went behind the house." "No," said John. "Uncle, I will not take your money, but here I will show you," taking from his pocket a lump of alum the size of a hen's egg. "This is it. I took a piece the size of the end of my finger, chewed it and swallowed it. It is a cure; it is a certain cure for any snake bite poison on earth."

In my travels over many Southern States I told hundreds of people about it, and, while I never had an opportunity to try it, I often had people tell me that they had tried the alum cure in a snake bite the other day, and it was all right—it cured the patient at once. One man told me he tried it and gave some spirits of ammonia at the same time, and did not know whether it was one or the other, or both, that did the work. So, after many years—about fifteen years ago—I saw a double-column write-up in the *Atlanta Constitution* from one of our missionaries in India, who was also a physician. He said one day he watched a snake juggler, or snake charmer, making his snakes dance. They were of the deadly cobra variety, hideous-headed reptiles, whose bite was certain death in a few minutes. And he saw the snakes get vicious and bite the keeper, when he would turn up a small bottle, drink some of the contents, and go on with the dance, apparently never getting sick. So our missionary prevailed on the snake keeper to tell him what the remedy was he drank from the vial. He told him it was the bile of the cobra snakes he had killed, and the bile of the cobra snake was a true antidote for cobra poison. As the missionary in India had to treat a great many snake bites every year, he tried the cobra bile, and found it an unfailing cure for the deadly poison from the cobra bite. He soon found he could not procure enough of the cobra bile, so he procured the bile of the blacksnake, a non-poisonous reptile, and he found it as true an antidote to the

poison of the cobra bite as the bile of the cobra snake was, and, still having more snake bites than he could procure snake bile to treat, he tried the bile of the ox, and found it as effective an antidote for the deadly cobra poison as either blacksnake or cobra bile. And when I read that I at once began to think why the alum was such an immediate cure for our Rocky Mountains rattlesnake, whose bite is so fatal, and other poisonous snakes. I know, as you may know, that alum taken into the stomach causes at once the bile tubes to force the bile out into the duodenal canal in gushing quantities, and enough will cause it to regurgitate into the stomach, and cause the patient to vomit, as in an old country woman giving her child alum and honey in case of croup until the child vomits, when the croup is relieved. So is it an unreasonable conclusion, where we know we can give one-third of a teaspoonful of powdered alum and two-thirds of a teaspoonful of white sugar, repeated every two hours in case of jaundice, and cause the bile to flow freely, more so than from any other remedy I ever gave, and fade out the jaundice in two or three days by opening up the catarrhal ductus choleductus, draining out the bile quicker than chionanthus or calomel, or all combined? Then I say is it unreasonable, or irrational, to presume that it is our patient's own bile that was caused by the doses of alum to flow out of the bile tubes and antidote the poison, and cure our patient so quickly, and save him all suffering usually attending the poisonous snake bite.

A hunter, in the mountains of Georgia, where his dogs are often bitten by the mountain rattlers, carries a pocketful of alum, and when one of his dogs are bitten he pours a quantity of alum down his dog's throat, and in a few minutes the dog goes on in the chase. Don't know where the hunter learned that alum is an antidote to snake bite, but here is an interesting story along the same line. I was relating the above to my friend, Dr. Mitchell, of Atlanta, and when I had finished, he said: "Well, Doctor, I can tell you something startling along that line, almost confirming all you say. Several years ago, in lower Georgia, I was called in to witness a test case of a rattlesnake having its poison teeth. A fakir came into our town selling a wonderful, all-healing and cleansing soap, and he had with him, as part of his show, about fifty of the largest diamond-sides rattlesnakes. He would let any one of them bite his naked arm anywhere from the shoulder down to his hand for a dollar. At last the community became skeptical, and he bet them a thousand dollars to a hundred dollars that his snakes—every one—had their poison fangs as he had caught them in the woods, and I was called in to witness the test. Now the fakir said to me, "Doctor, I have some snakes; they can select any one they please, and if that snake bites me I will die to prove a truth which I can not afford to do just now for their one hundred dollars. And if I take my antidote the poison will not hurt me, and that does not prove what I want, so let them select any animal they wish, and select any snake in the cage, and we will test it, and leave it to you to say whether they take my one thousand dollars or I take their one hundred." All right. So they selected a year-old boar hog and a large, old she rattlesnake (the fakir took her up in his naked arms), and put her in a dry goods box on the ground, with loose planks on one side, and then poked the snake until she was so mad that she was furious. They fed the hog up to the box, and when he was eating the corn, and had turned his head away from the box, they slipped the plank away and the snake, who was viciously mad, made a lunge at the hog and landed her fangs deep into his testicles, and in just nine minutes the hog was dead. One of the bystanders, who had lost ten dollars on the bet, picked up his dog, "Trip," and threw him on the snake, saying, "Now try 'Trip,'" and the snake landed on the jaw and in fourteen minutes "Trip" was a dead dog. The fakir took in the one hundred dollars. "Say your name is Mitchell, Doctor?" "Yes." "Are you related to old Dr. Mitchell, up somewhere in the States?" "Yes, I am his son." "Are you Jim Mitchell?" "Yes." "Then I am Joe Ramsey, your boyhood schoolmate."

"Well, Joe, tell me of this wonderful snake-bite cure you have, what it is and where you got it." "Doctor, it is only a strong solution of alum, with some am-

monia water in it. I got it in Coryell County, Texas." That was the next county to where I lived many years ago, and practiced medicine in the early '70s to 1890, when I came to Atlanta, where I have told hundreds of people the story about alum curing snake bite. I never had a chance to try it, but country people hearing of this told how they had tried it, and said it was a perfect cure. One man (and I believe he lived in Coryell County, Texas) told me he had tried alum with ammonia, and it certainly cured, but could not tell which did the work, but Joe Ramsey, who had picked up his cure in Coryell County, was using both successfully. Now, my dear doctors, do we need more proof than thirty-two years' success, and if that is all true, do we need to hunt further for a cure for snake bite poison? Or, perhaps we have in alum the specific for the poison of the tarantula, the centipede, the stinging scarpia, the hornet, the wasp, and the bee sting. I have not tried it, and ask all who have a chance to try it to let us know through the BRIEF. I know it was tried once where a man was quickly dying from the sting of the ocean ray—stinging ray, an ocean fish whose sting is almost fatal—and it relieved and cured him in a few hours, where all hope was gone. Try it, everyone who has an opportunity, and let us hear from all in America, Europe and India, through the grand old cosmopolitan, our MEDICAL BRIEF, and let the world know here is the hope of a remedy that is simple, indeed, and a cure for snake bites. If this is as good and sure a cure for all snake bites as I think, with the evidence I have from others, then we need nothing more, and the man who reads this and does not stop and think, remember it, and try it, reminds me of a man running after a street car, and after it stops for him to get on and sit down and ride, he just keeps on running. I believe that when we find out a good thing, use it. I know medicine is a science, but the practice of medicine is considered, by many very sensible people, to be a humbug, and there are so few specifics that for the purpose they should be used never failing, that when we find one, even though we do not know its original discoverer, only know that it is no animal serum or antitoxin, which, perhaps, were it not for the carbolic acid it contains, would be more correctly represented with the first four letters left off and that it is not from Berlin, but originated right here in our own country, perhaps among our farmers, or our rugged frontier mountain climbers of the far West, where rattlesnakes grow so large.

Obstetrics.

BY F. H. LONGLEY, M. D.,
North Platte, Neb.

I have been reading an article in the BRIEF, March number, page 223, "Arm Down and Head Behind the Shoulder," by C. D. R. Kirk, M. D.

Without comment, allow me to suggest an infallible method to adopt, that the late Professor John King, M. D., of Cincinnati, Ohio, gave me in 1866. I had several of those troublesome cases before Professor King gave me the "cue." By following his directions, we have no trouble with cases of the "arm down," etc.

For example, have your patient thoroughly anesthetized, and you find the right "arm down," you will advance with right hand extended, as though you were about to shake hands, continue to extend the right hand until you find one or both feet, and bring down the one or both. Should you find the left "arm down," introduce the left hand and you will make no mistake.
